Chapter 4

Photocatalytic Production of Hydrogen on Ni/NiO/KNbO₃/CdS Nanocomposites using Visible Light

Abstract

The photocatalytic production of H₂ from water splitting was demonstrated on Ni/NiO/KNbO₃/CdS nanocomposites using visible light irradiation at wavelengths > 400 nm in presence of isopropanol. The inherent photocatalytic activity of bulk-phase CdS was enhanced by combining Q-sized CdS with KNbO₃ and Ni deposited on KNbO₃. Enhanced activity is most likely due to effective charge separation of photogenerated electrons and holes in CdS that is achieved by electron injection into the conduction band of KNbO₃ and the reduced states of niobium (e.g., Nb(IV) and Nb(III)) are shown to contribute to enhanced reactivity in the KNbO₃ composites by mediating effective electron transfer to bound protons. We also observed that the efficient attachment of Q-size CdS and the deposition of nickel on the KNbO₃ surface increases H₂ production rates. Other factors that influence the rate of H₂ production including the nature of the electron donors and the solution pH were also determined. The Ni/NiO/KNbO₃/CdS nanocomposite system appears to be a promising candidate for possible practical applications including the production of H₂ under visible light.
Introduction

Hydrogen (H\(_2\)) production from water splitting using semiconductor photocatalysts has attracted considerable interest since the pioneering work of Fujishima and Honda,\(^1\) who discovered that water can be photo-electrochemically decomposed into hydrogen and oxygen using a semiconductor (TiO\(_2\)) electrode under UV irradiation. A large number of metal oxides and sulfides (e.g. TiO\(_2\),\(^1,3\) WO\(_3\),\(^4-6\) SrTiO\(_3\),\(^7,8\) ZnO,\(^9-11\) CdS,\(^12-17\) ZnS,\(^13,16,18,19\) niobates,\(^20-24\) and tantalates\(^25-28\)) have been examined as photocatalysts for hydrogen production from splitting water. However, the majority of the simple and mixed-metal oxides photocatalysts are primarily active for H\(_2\) production under UV irradiation (\(\lambda < 385 \text{ nm or } E_{bg} \geq 3.0 \text{ eV}\) present in only a small portion of solar light.

More recently, there is a focused effort on the development of photocatalysts that are capable of using visible light (\(\lambda = 400–700 \text{ nm}\)) for the photocatalytic production of H\(_2\) including transition metal doping (e.g., platinum,\(^29\) chromium,\(^30\) and vanadium\(^31\)) and nonmetallic element doping (e.g., nitrogen,\(^32-35\) sulfur,\(^36,37\) and carbon\(^35,38\)).

CdS, n-type semiconductor with \(E_g = 2.4 \text{ eV}\), has been shown to have photocatalytic activity for H\(_2\) production under visible light irradiation, although, sacrificial electron donors such as C\(_2\)H\(_5\)OH,\(^39\) HS\(^-\),\(^40,41\) or SO\(_3\)\(^2-\)\(^19\) are used to obtain measurable rates of H\(_2\) production and to avoid the photocorrosion of CdS in the presence of O\(_2\). On the other hand, the electronic levels and photoactivity of CdS can be tuned by changing or controlling particle size without changing the chemical composition. For example in the case of nanoparticulate ZnO, Hoffmann and co-workers\(^9,42\) reported a tenfold increase in photoefficiency for the photocatalytic production of hydrogen peroxide with a decrease in particle size from 40 to 23 nm. In another example, Hoffman et al.\(^43\) found an increase
in quantum efficiency for photo-polymerization of methylethacrylate with a corresponding decrease in particle size using Q-size CdS.

In order to enhance the photocatalytic activity of CdS, efforts have been made to combine CdS with other semiconductors having different band energies (e.g., TiO₂, ZnS, K₄Nb₆O₁₇, or K₂Ti₄O₉) since the coupling of two semiconductor particles with different energy levels is useful to achieve effective charge separation. For example in a colloidal TiO₂/CdS composite system, the electrons photogenerated from CdS band gap excitation can be transferred to the conduction band (CB) of TiO₂ particles, while the holes remain in the CdS particle. It is also observed that this charge separation in a colloidal composite system can accelerate the degradation of azo-dye and increase H₂ production in aqueous H₂S solution.

In this study, we synthesized nanocomposites of potassium niobate (KNbO₃) and CdS by solid-state reactions and investigated their properties and photoactivity for H₂ production under visible light irradiation (λ > 400 nm) in presence of isopropanol as an electron donor. KNbO₃ is used in optical waveguides, in nonlinear optical devices (e.g., frequency doubling and wavelength mixing), in piezoelectric devices (e.g., tunable frequency ultrasound transducers), in holographic image storage, and as a wide-band gap photocatalyst (ΔE₉ = 3.4 eV) because of its unusual chemical and physical properties. KNbO₃/CdS nanocomposites are characterized by XRD, SEM, TEM, UV-vis reflectance spectra and show better visible-light photoactivity for H₂ production than other composites (e.g., TiO₂ or K₄Nb₆O₁₇). Moreover, the efficiency of H₂ production is significantly enhanced by loading Ni on KNbO₃.
Experimental

Sample Preparation

Stoichiometric KNbO$_3$ was synthesized from Nb$_2$O$_5$ (Aldrich) and K$_2$CO$_3$ (Aldrich) in a standard solid-state reaction. K$_2$CO$_3$ and Nb$_2$O$_5$ were mixed together in a mortar at 1:1 mole ratio and the powdered mixture was pressed into a pellet at 27.6 Mpa and then heated at 650~925 °C for 10 hours with a heating and cooling temperature ramp of ±200 °C/h. With slight variations of the K:Nb mole ratio of 1:1.1 and a heating temperature at 1025 °C, a mixture of KNbO$_3$ and K$_4$Nb$_6$O$_{17}$ was obtained. Synthesis of K$_4$Nb$_6$O$_{17}$ was carried out for comparison using K$_2$CO$_3$ and Nb$_2$O$_5$ in the K:Nb mole ratio of 1:1.5 and calcination at 1150 °C for 10 hours. The crystal structures were confirmed by X-ray diffraction (XRD) at room temperature.

KNbO$_3$/CdS composite samples were prepared by stirring KNbO$_3$ powders in a 20 mL of ethanol of 2 x 10$^{-2}$ M Cd(CH$_3$COO)$_2$2H$_2$O for 1 day, followed by sulfurization with a 20 mL of ethanol of 2 x 10$^{-2}$ M Na$_2$S for 1 day. Composite samples were collected by filtration, which was followed by washing and subsequent drying.

Elemental nickel (Ni) and NiO (0.1~3.6 wt %) was loaded on the surface of KNbO$_3$ by a method that Domen and coworkers$^{23,53,54}$ reported. KNbO$_3$ samples were suspended in a Ni(NO$_3$)$_2$ aqueous solution for 1 day, followed by it being filtered, washed, and dried. The solid was reduced in H$_2$ atmosphere at 500 °C for 2 h, and subsequently oxidized in an O$_2$ atmosphere at 200 °C for 1 h. In the case of elemental Ni-loaded KNbO$_3$ samples (Ni/KNbO$_3$), the O$_2$ oxidation step was eliminated. The NiO-loaded KNbO$_3$ samples (NiO/KNbO$_3$) were obtained by complete O$_2$ oxidation at 500 °C for 1 h. A schematic flow chart is shown in Figure 4.1.
Characterization

The crystal structures of synthesized KNbO$_3$ samples were confirmed by a powder X-ray diffraction (XRD) using a Phillips diffractometer (X’pert Pro) with Cu-K$\alpha$ radiation. Diffuse reflectance spectra were obtained with UV-vis spectrometer (Shimadzu UV-2101PC) and were converted from reflection to absorption spectra by the Kubelka-Munk method. Brunauer-Emmett-Teller (BET) surface area analyses were also performed to compare the surface areas of KNbO$_3$ samples that were prepared under different conditions. Microstructures and composition were also analyzed with a LEO 1550VP Field Emission Scanning Electron Microscope (SEM) and Philips EM201 Transmission Electron Microscope (TEM). Inductivity Coupled Plasma-Mass Spectrometry (HP 4500 ICP-MS) was used to determine the amounts of Ni$^{2+}$ and Cd$^{2+}$ adsorbed on the surface of KNbO$_3$. Potassium ions released from KNbO$_3$ during ion-exchange with Ni$^{2+}$ were determined by Dionex DX-500 Ion Chromatography system. X-ray Photoelectron Spectroscopy (XPS) was used to observe the changes in the oxidation state of Nb species and Ni species adsorbed on the surface of KNbO$_3$ with Al K-\(\alpha\) radiation.

Photocatalytic Reaction

Photocatalytic reactions for hydrogen production were carried out in an air-tight reactor vessel under visible light irradiation (\(\lambda > 400\) nm). Catalyst samples (0.2 g) were suspended in 50 mL of a water/isopropanol mixture (30 v/v %) in a Pyrex glass reactor. Samples were purged with Ar or N$_2$ gas for 30 min before reaction in order to eliminate dissolved O$_2$. A high-pressure 500 W Hg-Xe arc lamp in combination with a 400 nm cut-off filter was used as the primary light source. The intensity of incident
light was determined by ferrioxalate actinometry to obtain quantum yields for H₂ production. The amount of H₂ evolved during photolysis was analyzed by GC/TCD (HP 5890, N₂ carrier) with a molecular sieve column (30 m × 0.32 mm × 12.00 μm).

Results and Discussion

Ni/NiO/KNbO₃/CdS Nanocomposite Characterization

Figure 4.2 shows XRD patterns of synthesized KNbO₃ under different calcination temperatures and mole ratios. XRD pattern for KNbO₃ calcined at 925°C with 1:1 mole ratio of K:Nb (Figure 4.2(a)) shows exactly same 2θ peaks that correspond to standard KNbO₃. Samples calcined over the range of temperature from 650 to 925°C also show the same peak patterns. However, a sample produced at 1025 °C with 1:1.1 mole ratio of K:Nb (Figure 4.2(b)) has an extra 2θ peaks that are attributed to potassium hexaniobate (K₄Nb₆O₁₇). K₄Nb₆O₁₇ has a perovskite structure similar to KNbO₃, but it consists of a layered structure composed of two different types of niobate sheets. The material structures are also confirmed by SEM images. A layered structure is only observed for the sample calcined at 1025°C by SEM as shown in Figure 4.3. The diffraction peaks of KNbO₃ samples are more intense and sharper, with an increase in calcination temperature. The broadening of XRD peaks at low calcination temperatures may be due to smaller crystallite size. The particle sizes of KNbO₃ at different calcination temperatures can be estimated with the Scherrer equation; the estimated particle sizes were 28, 32, and 39 nm for KNbO₃ samples prepared at 650 °C, 775 °C and 925 °C, respectively. BET surface areas were also measured at 4.35, 3.08, and 2.14 m²g⁻¹ for 650 °C, 775 °C, and 925 °C samples, respectively, and it is apparent that the
specific surface area decreases with an increase in calcination temperature. Furthermore, there appears to be no observable structural difference between KNbO$_3$ samples before and after Ni deposition or with the addition of nanoparticulate CdS. Figure 4.4 is the TEM picture of nanocomposite sample of Ni/NiO/KNbO$_3$/CdS which shows that Ni or CdS nanoparticles were loaded on the surface of KNbO$_3$.

Figure 4.5 shows the light absorption properties of nanocomposite samples. The KNbO$_3$/CdS nanocomposite absorbs visible light at $\lambda > 400$ nm. This is primarily due to the band gap excitation of Q-size CdS, since KNbO$_3$ does not absorb visible light. The respective band gaps are estimated to be 3.4 eV and 2.6 eV for KNbO$_3$ and Q-CdS, from the plots of Kubelka-Munk functions vs. photon energy. It should be noted that absorption edge of Q-size CdS synthesized for CdS/KNbO$_3$ nanocomposite is blue-shifted from absorption edge of bulk CdS particles.$^{43}$

The synthesized KNbO$_3$ samples were suspended in an aqueous Ni(NO$_3$)$_2$ solution for 1 day to load Ni$^{2+}$ as a co-catalyst. ICP-MS and IC results show that most of Ni$^{2+}$ ions are adsorbed on the surface of KNbO$_3$ particles and some of them are ion-exchanged with K$^+$ ions located in KNbO$_3$ framework. However, in synthesis of CdS nanoparticle on KNbO$_3$ surface, only 20–30% of Cd$^{2+}$ ions are adsorbed on the surface and ion exchange with K$^+$ are not observed. Then Ni$^{2+}$-adsorbed (or ion-exchanged) KNbO$_3$ samples were treated under proper conditions, i.e., H$_2$ reduction at 500 °C followed by O$_2$ oxidation at 200 °C. After thermal reduction by H$_2$, the doped samples turned gray from the initial white undoped KNbO$_3$. However, oxidation at 500 °C converts elemental nickel to NiO with a corresponding change in color from gray to light yellow. XPS analysis of the various samples was used to identify the oxidation states of Ni in each sample.
Photocatalytic H₂ production

The measured H₂ production rates in illuminated aqueous isopropanol solutions under visible light with CdS, KNbO₃, Ni/NiO/KNbO₃, and Ni/NiO/KNbO₃/CdS composites are compiled in Table 4.1. The naked KNbO₃, nickel-doped KNbO₃, and Ni/NiO/KNbO₃, samples showed no activity for H₂ production under the visible light since its band gap energy (3.4 eV) was larger than the excitation energies (λ > 400 nm). Simple Q-CdS nanoparticle suspensions produce H₂, but at very low rates. However, H₂ production rates increase significantly in the KNbO₃/CdS nanocomposites. This may be due to effective charge separation of electrons and holes in illuminated CdS, with electron injection into the conduction band of KNbO₃ possible in the KNbO₃/CdS nanocomposites. H₂ production with TiO₂ (Degussa P-25)/CdS nanocomposites was also performed for comparison. TiO₂/CdS had lower H₂ production activity than KNbO₃/CdS. H₂ production rates for the KNbO₃/CdS nanocomposites were enhanced significantly in the presence of the deposited Ni/NiO co-catalysts. Ni most likely serves to collect conduction band electrons. However, a significant enhancement of H₂ production rate was not observed in Pt deposited KNbO₃ samples (Pt/KNbO₃/CdS) as compared to Ni/KNbO₃/CdS nanocomposites. We also synthesized potassium hexaniobate (K₄Nb₆O₁₇) for comparison because K₄Nb₆O₁₇ is known as a good photocatalyst for H₂ production under UV light irradiation. However, the result shows that KNbO₃/CdS nanocomposite produces more H₂ than K₄Nb₆O₁₇/CdS under visible light irradiation.

The enhanced reactivity of the KNbO₃ nanocomposites may be due to involvement of the reduced states of niobium and/or oxygen vacancies that allow for the photoexcitation
of mobile electrons with visible light. For example, Ewart et al.\textsuperscript{55} reported that mobile electrons are generated in electrochemically reduced and Fe-doped KNbO\textsubscript{3} upon excitation at 532 nm. The electrons photoexcited at 532 nm had lifetimes of 4 ns and electron mobilities of 0.5 cm\textsuperscript{2} V\textsuperscript{-1} s\textsuperscript{-1}. They concluded that the photoexcited electrons are trapped within 4 ns (i.e., loss of detectable mobility), however, the trapped-state electrons are thermally activated on a millisecond timeframe and eventually recombine with the internal donor states. Kesselman et al.\textsuperscript{56} observed a similar reduction in Nb\textsubscript{2}O\textsubscript{5}/TiO\textsubscript{2} composites that were reduced over hydrogen at high temperatures. Reduction of Nb\textsubscript{2}O\textsubscript{5} is known to form a variety of phases such as Nb\textsubscript{12}O\textsubscript{29}, Nb\textsubscript{22}O\textsubscript{54}, Nb\textsubscript{25}O\textsubscript{62}, and Nb\textsubscript{47}O\textsubscript{116} that involve partial oxygen loss coupled with the formation of Nb(IV). Therefore, the longer lifetimes ($\tau_{tr} >$ ms) of the trapped electrons may contribute to the higher reduction rates for bound protons or hydroxides. Similar mixed valence state phase should coexist within the framework of reduced KNbO\textsubscript{3} and contribute to the photo-excitation of electrons and to the overall photoactivity with visible light. The Ni/NiO/KNbO\textsubscript{3} samples were thermally treated at 500 °C under H\textsubscript{2} atmosphere to reduce Ni\textsuperscript{2+} to elemental nickel. This treatment step may lead to creation of oxygen vacancies or formation of the reduced states (e.g., Nb(IV) and Nb(III) states) of niobium. The thermal treatment of pure, white KNbO\textsubscript{3} at 500 °C under H\textsubscript{2} produced a light gray product that is consistent with Nb(V) reduction. We performed XPS analysis to compare the oxidation states of Nb between KNbO\textsubscript{3} samples before and after H\textsubscript{2} reduction, however, the reduced states were not readily observed. However, it was measured that reduced states of Nb are formed during the photolytic reaction. Another relevant feature of the metal niobates (e.g., LiNbO\textsubscript{3}\textsuperscript{57} and KNbO\textsubscript{3}\textsuperscript{58}), which is critical for
electro-optic and photorefractive applications, is the activation of surface protons (i.e., protons bound in hydroxyl ions, \( \cdot \text{OH} \)). The hydroxyl bound protons have activation energies in the range of 1 eV for mobility in KNbO\(_3\) crystals.

In light of the above photophysical properties related to surface hydroxyl groups, an alternative pathway may involve excitation of reduced KNbO\(_3\) with visible light followed by conduction band reduction of surface bound protons on KNbO\(_3\). The pH of zero point of charge, pH\(_{\text{zpc}}\), of KNbO\(_3\) was measured ~ pH 3.2, thus KNbO\(_3\) surface may be dominated by >NbOH and >NbO\(^-\) under our optimal experimental conditions (~ pH 8). Given this situation, we can write the following set of reactions that may result in H\(_2\) production on KNbO\(_3\) surface sites or Ni/NiO/KNbO\(_3\) composite sites:

\[
\text{KNb(V)O}_2 \xrightarrow{\text{T=500°C, H}_2} \text{KNb(IV)O}_2 \quad (4.1)
\]

\[
\text{KNb(IV)O}_3 + h\nu \xrightarrow{\lambda=330\text{nm}} e^-_{cb} + h^+_h \quad (4.2)
\]

\[
>N\text{b(IV)O} + \text{H}_2\text{O} \xleftrightarrow{\text{2H}_2\text{O}} 2>N\text{b(IV)OH} \quad (4.3)
\]

\[
>N\text{b(IV)OH} \xrightarrow{k_1} >N\text{b(IV)O}^- + H^+ \quad (4.4)
\]

\[
>N\text{b(IV)OH} + e^-_{cb} \xrightarrow{\text{e}_{cb}} >N\text{b(IV)O}^- + H^- \quad (4.5)
\]

\[
2\text{H} \xrightarrow{} \text{H}_2 \quad (4.6)
\]

In addition, we compared three different procedures for attachment of CdS particles on the KNbO\(_3\) surface as shown in Figure 4.6. To form KNbO\(_3\)/CdS nanocomposites, we first added Cd\(^{2+}\) ions in KNbO\(_3\) suspension, and then we added sulfide (HS\(^-\)/S\(^{2-}\)) ions after stirring for 1 day (Figure 4.6(a)). ICP-MS results show that only 20–30 % of the Cd in CdS particles are directly synthesized on the KNbO\(_3\) surface and the remainder of
the CdS particles are suspended freely in the solution. One sample was prepared by mechanical mixing of CdS and KNbO₃ by addition of KNbO₃ after Q-CdS synthesis in ethanol (Figure 4.6(b)) and another sample has only CdS adsorbed on the KNbO₃ surface by removing free Cd²⁺ ions in suspension before adding S²⁻ ions (Figure 4.6(c)). The CdS surface adsorption sample (Figure 4.6(c)) shows reasonable photoactivity even though the amounts of CdS are quite small (20~30 %) compared to samples having CdS synthesized both on KNbO₃ surface and in solution (Figure 4.6(a)). As a consequence, we conclude that direct CdS contact with the KNbO₃ surface plays an important role for effective charge separation with increased H₂ production rates, although externally mixed sample (Figure 4.6(b)) also has measurable H₂ production rates. From these results, we can infer that Q-CdS particles are attached to the surface of KNbO₃ under our experimental conditions (~ pH 8) even though CdS was synthesized initially in solution phase.

The KNbO₃ surface is negatively charged under the pH conditions of our experiments since the pHₜpc of KNbO₃ is measured ~ pH 3.2. The actual determination of pHₜpc of the nanoparticulate CdS colloids is more difficult. Park and Huang⁵⁹ reported a pHₜpc = 7.5 for colloidal CdS based on electrophoretic mobility measurements and acid-base titrations. At an ionic strength of \( \mu = 0.05 \) M, they determined that \( \text{pK}_{a1} = 6.1 \) and \( \text{pK}_{a2} = 9.0 \) for [Cd²⁺] = 2.5 μM and \( \sigma_0 = 20 \text{ mC cm}^{-2} \). Liu and Huang⁶⁰ subsequently reported a pHₜpc for cubic CdS of 7.0 and pHₜpc = 7.5 for hexagonal CdS. In contrast, other researchers⁶¹-⁶³ have reported substantially lower values for the pHₜpc for CdS in aqueous suspensions. Under experimental conditions that were quite different from those employed by Park and Huang,⁵⁹ Nicolau et al.⁶³ determined a pHₜpc = 1.8 for 0.01
M Na₂SO₄ and KCl as background electrolytes based on electrophoretic mobility measurements. Guindo et al.⁶² found even lower values of pHₑₚₑ between 1 and 1.5 for spherical CdS particles differently prepared. However, they pointed out that the IEP (isoelectric point) was sensitive to the specific surface characteristics of CdS that depends on the degree of oxidation or aging as noted by the shift in IEP to higher values for samples that were synthesized over longer periods of time. According to our observations, it may be true that pHₑₚₑ of CdS is relatively high value under our experimental conditions, so that CdS colloid in solution are positively-charged and then electrostatically attracted to the negatively charged KNbO₃ particles under our experimental pH condition.

The rates of H₂ production on the four-component composite, Ni/NiO/KNbO₃/CdS are compared to the three-component composite containing only Ni or NiO. The data presented in Figure 4.7 shows that elemental Ni on KNbO₃ is a more active species than NiO on KNbO₃ to improve H₂ production, although its external surface is partially oxidized to NiO. However, the H₂ production rates are not greatly enhanced in the three-component composite containing only NiO. This tendency is consistent with previous results obtained for Ni/NiO loaded onto SrTiO₃ as reported by Domen et al.⁵³ They reported that Ni/NiO/SrTiO₃ produced substantially more H₂ from aqueous methanol than the simpler NiO/SrTiO₃ system under UV irradiation. They concluded that the presence of Ni metal in contact with the SrTiO₃ surface plays an important role in the H₂ production activity. Domen et al.⁶⁴ also found small amounts of H₂ evolved under the band gap irradiation of Ni/SrTiO₃. They attributed their low activity to loss of Ni by release of Ni²⁺ due to oxidation of Ni metal by direct hole transfer from SrTiO₃.
during band gap irradiation. In contrast, our results show that the three-component Ni/KNbO₃/CdS composite can produce a comparable amount of H₂ compared to the four-component Ni/NiO/KNbO₃/CdS composite. In both the 3- and 4-component catalyst, the primary absorption occurs at \( \lambda > 400 \text{ nm} \) (compared to SrTiO₃ with \( \lambda < 400 \text{ nm} \)) with CdS as a chromophore. Thus, elemental nickel deposited on KNbO₃ is unlikely to be directly oxidized by holes in our composite material.

As shown in Table 4.1, the highest H₂ production rates were obtained with a Ni-deposition level of 0.1 wt. % as \( (\text{Ni}_T = \text{Ni} + \text{NiO}) \), and above this level, enhancement due to nickel deposition was marginal. However, we observed the enhanced H₂ production with higher wt% of Ni deposition on KNbO₃ samples prepared at low calcination temperatures. The increase of photoactivities with 0.5 ~ 1.0 wt. % Ni-loaded on KNbO₃ prepared at low calcination temperatures may be only due to a simple increase in the total reactive surface area. It is noted that KNbO₃ sample mixed with \( \text{K}_4\text{Nb}_6\text{O}_{17} \) structure which was calcined at 1025°C produces comparable amounts of H₂ to KNbO₃ samples calcined at 925°C.

We observed fairly dramatic color changes taking place during irradiation of the Q-size CdS and the CdS nanocomposite materials. In all cases, the catalysts suspensions are yellow before illumination because of CdS chromophore. However, after exposure to a focused beam of light at \( \lambda > 400 \text{ nm} \), the color changes very quickly to a silver gray. As the color changes from yellow to gray, H₂ production is observed as a steady stream of gas bubbles rising up in the photolysis cell. The observed color change may be due to the rapid photoreduction of Cd(II) to Cd(I) and then to Cd(0) on the surface of CdS in the absence of oxygen. There is also some probability that S(-II) in the CdS matrix is
also oxidized partially by trapped valence band holes to form S(0) and eventually polysulfide ion ($S_{2}^{2-}$). Upon exposure to oxygen, the yellow color is regenerated over several hours with the return of yellow CdS on the nanocomposite structures.

Apparent quantum yields, $\phi$, for $H_2$ production, were determined as follows:

$$\phi = \frac{\frac{dm_{H_2}}{dt}}{I_{abs}} \times 2 \quad (4.7)$$

where $\frac{dm_{H_2}}{dt}$ is an initial production rate of $H_2$ (mol s$^{-1}$) and $I_{abs}$ is photon absorption rate in units of Einstein s$^{-1}$ (mol(e$^{-}$) s$^{-1}$). We also considered the fact that two electrons are consumed to produce one hydrogen molecule from two protons for quantum yield calculation. The photon flux through the cell was $2.3 \times 10^{17}$ photons s$^{-1}$, as determined by ferrioxalate actinometry with an apparent quantum yield for $H_2$ production of 4.4 % for $\lambda > 400$ nm. It should be noted that the amount of light scattered from nanocomposites suspension was not considered here and therefore actual quantum yield may be higher.

**Photocatalytic $H_2$ Production Under Natural Sunlight**

Substantial amounts of hydrogen gas are also produced readily using natural sunlight as the irradiation source. For example, the 4-composite was exposed to solar light between 11:30 am and 3:30 pm on the roof of W. M. Keck Laboratories at Caltech on August 13, 2006. Experimental procedures were identical to those employed in the controlled laboratory experiments except for the use of different types of pyrex reactors. As shown in Figure 4.8, $H_2$ is readily produced from aqueous isopropanol solutions under natural sunlight; however, the amount of $H_2$ produced is actually larger than that
produced over the same period of time under UV light irradiation in the laboratory. This simple demonstration illustrates the potential of practical application of Ni/NiO/KNbO₃/CdS nanocomposite for H₂ production with sunlight.

Influence of Solvent Composition on Photocatalytic H₂ Production

The relative effects of a variation of solvent/water mixtures on H₂ production for KNbO₃/CdS at \( \lambda > 400 \) nm are illustrated as shown in Figure 4.9. 30 v/v% of isopropanol (IPA), ethanol (EtOH), and methanol (MeOH) solution were used in the photoreaction. The order of photoreactivity is IPA > EtOH > MeOH, which is in inverse order of their dielectric constants (i.e., \( \varepsilon_{IPA} = 19 < \varepsilon_{EtOH} = 24.3 < \varepsilon_{MeOH} = 33 \)).

Alcohols function primarily as hole traps that prevent rapid electron-hole recombination. The presence of an electron donor other than water is crucial for photocatalytic H₂ production, since little H₂ is produced without added electron donors even under UV light irradiation. However, the interaction of the various electron donors with the charged CdS surface will also depend on their chemical and physical properties. Alcohols have substantially lower dielectric constants than H₂O (\( \varepsilon = 80.4 \)). As a consequence, we predict that the relative thickness of the electrical double layer (EDL) should decrease when alcohols are added. The EDL thickness should decrease in the order of dielectric constants, as given by the Debye equation:

\[
\kappa \equiv \left( \frac{2F^2 \mu}{\varepsilon \varepsilon_0 RT} \right)^{0.5}
\]

(4.8)

where \( \varepsilon \) is the dielectric constant of the solvent or mixed solvent system, \( \varepsilon_0 \) is the permittivity of free space (\( 8.854 \times 10^{-12} \) C² J⁻¹ m⁻¹), \( \mu \) is the ionic strength of the
background electrolyte (mol m⁻³), R is the gas constant (8.314 J mol⁻¹ K⁻¹), T is temperature in units of K, and F is the Faraday constant (96485 C mol⁻¹). Electrical double layer compression will enhance the physicochemical interaction of the electron donors with the charged CdS surface. Thus, a more efficient hole trapping by the electron donors should increase H₂ production rates.

We note that SO₃²⁻ and S²⁻ are also frequently used as sacrificial donors to prevent the photocorrosion of metal sulfide semiconductors;¹⁹,₄₆,₄₇,₆₅ however, the H₂ production rate of KNbO₃/CdS nanocomposites with the addition of 0.01 M SO₃²⁻ and 0.1 M S²⁻ was very low relative to adding alcohols as electron donors.

**Influence of pH on Photocatalytic H₂ Production**

Without the addition of acid or base, the pH of the KNbO₃/CdS suspensions in ROH/H₂O is between pH 8 and 9. The pH-dependent production of H₂ from aqueous isopropanol solution under visible light is shown in Figure 4.10. The highest production rates of H₂ were obtained in the circumneutral pH region, while the rates of H₂ production decreased at higher and lower pH.

The relative attachment of Q-CdS on the KNbO₃ particles should be influenced by the KNbO₃ and CdS surface charges. Since the pH_{zpc} value of KNbO₃ was determined to be 3.2, the KNbO₃ surface is negatively charged at both neutral and alkaline pH (i.e., pH > pH_{zpc}) and is positively charged at very acidic pH (i.e. pH < pH_{zpc}). In case of Q-CdS, pH_{zpc} value varies from pH 1 to 7, according to the structure and surface characteristics of CdS, and the types and concentrations of background electrolytes. However, we assume that the pH_{zpc} of CdS is more likely to be high under our conditions to possibly account
for the rapid attachment of CdS colloids to the larger KNbO₃ particles (Figure 4.6(c)). Therefore, at circumneutral pH, positively charged CdS can be adsorbed onto the negatively charged KNbO₃ surface. At low pH, the surface charges of CdS and KNbO₃ would be positive, and at high pH, both particles are negatively charged so that effective contact and charge transfer from CdS to KNbO₃ is less likely to occur at extreme pH. Furthermore, proton ion-exchange also occurs for KNbO₃ samples under acidic conditions. K⁺ ions in the framework of KNbO₃ may be ion-exchanged with H⁺ ions, and a proton-exchanged form, K₁₋ₓHₓNbO₃, may have different structure and physicochemical properties from the original KNbO₃ materials. We prepared K₁₋ₓHₓNbO₃ samples by stirring in 0.5 N H₂SO₄ solutions for several days followed by washing, filtration, and drying, and tested photoactivity of K₁₋ₓHₓNbO₃/CdS nanocomposites for H₂ production. In circumneutral pH region, K₁₋ₓHₓNbO₃/CdS nanocomposites show extremely low H₂ production rates (~ 2.8 μmol h⁻¹ g⁻¹). Therefore, we conclude that proton-exchanged KNbO₃ can be formed in low pH and it may cause low photoactivity of KNbO₃ for H₂ production in acidic pH.

**Conclusions**

Efficient H₂ production was obtained with Ni/NiO/KNbO₃/CdS composites with visible light irradiation (λ > 400 nm). H₂ production rates were higher than TiO₂/CdS or K₄Nb₆O₁₇/CdS composites. Partially reduced states of niobium (e.g., Nb(IV) and Nb(III)), which are generated during Ni formation under H₂ and by photoreduction, may contribute to the enhanced reactivity of the KNbO₃ composites. Aliphatic alcohols (methanol, ethanol, isopropanol, etc.) serve as alternative electron donors and modified
the near surface environment via electrical double layer compression. The solution pH also influences the rate of photocatalytic H₂ production, with the highest H₂ production rates obtained at circumneutral pH. In addition, the 4-component nanocomposite (Ni/NiO/KNbO₃/CdS) produces H₂ rapidly under natural sunlight. Our findings suggest that use of solar energy for photocatalytic water splitting with this developed photocatalyst system may give a promising source for hydrogen fuel.
