ACKOWLEDGEMENTS

The author wishes to express his thanks and appreciation to Dr. Clark B. Millikan under whose direction this investigation was conducted and to Dr. D.A. Morelli and Mr. R.W. Bell for their technical advice and helpful criticisms.

The author also wishes to thank the members of the GALCIT 10 ft. Wind Tunnel staff for their assistance on computing and plotting the data, and his fiance, Miss Elizabeth Friberg, for spending many evenings typing and re-typing the original manuscript.

ABSTRACT

In this investigation a study was made of the effects of boundary layer control on a 10% thick, double-wedge airfoil located between endplates. In particular, the study centered around a "high-lift" investigation in order to obtain an optimum configuration for the specific airfoil. The double-wedge airfoil was used since:1) it is a "high speed" airfoil, and 2) it has poor maximum lift and stalling characteristics.

The model used was equipped with a nose flap and a slotted trailing edge flap, both of 20% wing chord, and two suction slots, one aft of the nose flap (20% chord) and the other at the 70% wing chord. Five suction quantities were used on all possible configuration combinations. The maximum lift coefficient obtained was $C_{\rm L_{max}} = 2.149$ at an angle of attack of 21° and a suction quantity equal to $C_{\rm Q} = 0.0071.*$ For this particular configuration, the approximate value of the horsepower required to supply the necessary suction quantity was determined. In addition to the force and moment tests, tuft studies of flow of the "optimum" configurations were made and reported.

^{*} Configuration: Nose flap deflected 30°; trailing edge flap deflected 30°; slot \mathcal{A}_1 (forward slot)

I. INTRODUCTION

As the speed of the airplane increases, the need for a thinner airfoil becomes greater. Thin, symmetrical airfoils, and especially double-wedge airfoils, have inherently unfavorable low speed characteristics such as a low maximum lift and a low angle of stall. In view of this, many methods have been employed to improve these characteristics.

The most logical method, and the one first used, was to employ a nose flap since the separation from the leading edge starts at a low angle of attack. This configuration in a double-wedge airfoil favorably changed the characteristics, but the magnitude of the changes was not large enough to be considered adequate for practical purposes. The application of a trailing edge flap further increased the maximum lift, but it tended to counteract the increase in angle of stall obtained by the nose flap. Something else was needed to supplement the improvement due to the flaps.

For many years, the knowledge of boundary layer control and the advantages associated with it were known, but not until the advent of supersonic wings has it become exceedingly important. It is the purpose of this investigation to test a 10% thick double-wedge airfoil with nose flap and trailing edge flap under the influence of boundary layer suction. It is known by theory and by test that if the slow moving boundary layer is removed by suction or re-energized by blowing, separation can be delayed and a substantial lift increase obtained. Since for thin, symmetrical sections separation begins at the leading edge, a boundary layer slot was located at approximately the 20% wing chord, at the junction of

INTRODUCTION (cont'd)

the leading edge flap and the upper surface of the airfoil. Also with the airfoil at moderate angles of attack, an unfavorable pressure gradient occurs at the rear portion of the airfoil and moves forward steadily. In an attempt to re-establish a favorable pressure gradient over this aft portion, another boundary layer suction slot was located at the 70% wing chord, inclined 30° to the surface of the airfoil. As an added assistance a slotted trailing edge flap was used instead of a split or zap flap in the hope that this flap configuration would also improve the basic configuration.

The purpose of these investigations is to study the effect of boundary layer control on the characteristics of the basic double-wedge airfoil. Five suction quantities and two slot locations were tested with all possible configurations of the basic airfoil.

An attempt was made to determine the horsepower required to apply the boundary layer suction data obtained on the model to a full scale prototype airplane of the following dimensions:

```

INTRODUCTION (contid)

The method followed was that suggested by Sir Handley Page. The results are presented herein on page 36.

As a result of these investigations an insight into future research was obtained. Suggestions along this line appear in the discussion of the test results.

II. DESCRIPTION OF TEST SET-UP

The model was tested in the closed throat Merrill Wind Tunnel of the Guggenheim Aeronautical Laboratory at the California Institute of Technology. The dimensions of the test section of this tunnel are 32" x 45". At the time of testing, the tunnel had three wire screens located just ahead of the contraction section primarily for the purpose of producing low turbulence flow.

The model tested was a 10% thick, double-wedge airfoil with a 20% chord nose flap and a 20% chord slotted trailing edge flap. To remove the boundary layer there were two slots, the front slot being located at the 20% wing chord or hinge line of the nose flap, and the rear slot being located at the 70% wing chord. The critical dimensions of the model are: wing chord = 8 inches; span = 24 inches; slot width = 0.05 inches. To approximate two-dimensional flow the model was installed between endplates of $6\frac{1}{2}$ inch radius. Attached to the outside of the endplates were the 3/4 inch I.D. brass air pipes which carried off the boundary layer to the outside of the tunnel and also acted as the attachment points for the model support system (See photos 1,2,and 6).

The double-wedge airfoil was set on the supporting struts, 15 3/4 inches from the leading edge of the tunnel working section. The air pipes were connected to the air suction system by 8 inch sections of rubber tubing. A spring of 1/16 inch wire was placed within each of these flexible tubes to prevent collapse by the suction. From here the suction system, consisting of 3/4 inch piping, from each side of the tunnel, went through a common gate valve to a 50 gallon drum located beneath the tunnel aft of the

DESCRIPTION OF TEST SET-UP (cont'd)

atmospheric slot (see figure 3). This drum acted as a "pressure reservoir" to prevent surging and maintain a constant suction pressure. The suction pressure was maintained by two Black and Decker Industrial Vacuum Cleaners whose characteristics are shown in figure 4. These were connected to the lower part of the reservoir (see photos 7 and 8) and the quantity of flow was regulated by the gate valve ahead of the inlet to the reservoir. The air flow was measured by setting a standard pitot tube in the outlet pipe of the cleaners.

For each test a certain total pressure (in inches of alcohol)
was set on the "blowers", and maintained constant during the run.
The model was then run through a sequence of angles of attack to
determine the angle of stall. Once this was determined, the run
was made, taking only lift data for 8 to 10 angles through the stall.
In many cases, abrupt and severe buffeting prevented testing at any
angles above the stall.

Throughout the investigation, except for the runs pertinent to the Reynolds number effect, the tunnel dynamic pressure was kept at q = 20 lb/ft². This value was chosen after an investigation of Reynolds number effects and a consideration of an optimum value for the maximum suction quantity coefficient.

For the tuft runs made at the end of the investigation, a window of plexiglas was located in the ceiling of the test section, through which pictures were taken using the normal lighting of the test section (two white flourescent tubes in upper corners of the test section).

DESCRIPTION OF TEST SET-UP (cont'd)

For those runs in which only slot A_1 was used, the rear slot was sealed by cellophane tape on the upper surface of the airfoil. When slot A_2 was used alone, slot A_1 was sealed with cellophane tape applied to the exterior side of the channel located inside of the model. This was done since the tape would otherwise tend to produce an early separation near the leading edge.

III. METHOD OF EXPERIMENTAL PRESENTATION

The data obtained in the investigation were reduced to dimensionless coefficient form and are presented as plotted points connected by suitably faired curves. Only lift component data were taken and in no instance were any corrections applied to the data.

Possible corrections applicable to the data could result from one or more of the following factors: 1. supporting struts, 2. wind tunnel walls, 3. tunnel flow inclinations, 4. tunnel flow irregularities. The supporting struts for the model were located outside of the endplates on the airflow pipes; therefore the presence of the struts should have a negligible effect on the lift data. A correction for the presence of the tunnel walls is not necessarily negligible, but due to the "two-dimensional" set-up of the model, the magnitude of such a correction is unknown. Tunnel flow inclination can also have an appreciable effect on the data by increasing or decreasing the apparent angle of attack*. The calibrations of the Merrill Wind Tunnel show a negligible flow inclination in the model test section. Possible factors under item 4 include variation of tunnel velocity across the working section, longitudinal pressure gradient in the working section, and turbulence level. The first two factors have been shown to exist by preliminary calibrations of the Merrill Wind Tunnel. Incomplete information on and understanding of the corrections led to their being neglected.

^{*} $\mathcal{Q}_{\rm g}$ = 0° was set by leveling the wing chord line inscribed on the endplates; $\mathcal{Q}_{\rm g}$ = 0° is defined as the angle of attack at which $c_{\rm L}$ = 0 (for symmetrical airfoils).

METHOD OF EXPERIMENTAL PRESENTATION (cont'd)

From figure 8, it is seen that at $\mathcal{C}_{\rm g}$ = 0°, the lift coefficient ${\rm C_L}$, is not equal to zero but to 0.050. Since the model is symmetrical and there exists no flow inclination, the model was examined for possible errors. Upon investigation, the wing chord line was found to be inclined upward at an angle of 0.3° from the line inscribed on the endplates and taken to be the wing chord. It was also discovered that both the nose flap and the slotted trailing edge flap were warped downward (except at the ends) causing an effective camber in the airfoil. The effects of these conditions add up to a positive lift coefficient at $\mathcal{C}_{\rm g}$ = 0° of about the magnitude observed.

The data obtained are presented in five groups of plots:

- Effects of Suction shows increase of maximum lift as suction is increased
- 2. Effects of Slot Location shows change of maximum lift for variation in slot location and combination
- 3. Flap Effectiveness shows increase of maximum lift for increase in flap deflection
- 4. Variation of Maximum Lift with Flap Deflection shows change in maximum lift with nose flap deflection for a given trailing edge flap deflection
- 5. Variation of Lift with Suction Quantity shows change in lift at a given angle of attack as the suction quantity is increased (slot location as a parameter).

For groups 2,3, and 4, only the data for zero and maximum suction were used.

The tuft sketches (figures 73 to 81), appearing at the end of this

METHOD OF EXPERIMENTAL PRESENTATION (cont'd)

report were made using the tuft photographs as a guide. The solid-dotted lines indicate that the area to the rear of the dots has a turbulent boundary layer and the stall is imminent; the solid-dashed lines indicate that the flow has already separated from the airfoil in the area to the rear of the dashes. The photographs for only one run are included in the report to serve as an example and a check.

IV. DEFINITION OF CONFIGURATION SYMBOLS

- S = Basic 10% double-wedge airfoil; span is 24 inches, chord is 8 inches; configuration includes circular endplates and air flow ducting from model through tunnel wall
- F_N = 20% chord nose flap; deflection is 15° or 30° from wing chord plane (see figure 2)
- F_S = 20% chord slotted trailing edge flap; deflection is 30° or 60° from the wing chord plane (see figure 2)
- 1 = Boundary layer control slot located on wing upper surface at the junction of the nose flap and wing surface; width = 0.05 in.
- A₂ = Boundary layer control slot located on the wing upper surface at the 70% wing chord; slot is inclined 30° to the wing upper surface; width = 0.05 in.

V. DIMENSIONAL DATA

MODEL

Span = 24 inches

Chord = 8 inches

Wing Area = 1.33 ft²

Slot Width = 0.05 inches = 0.0042 ft

Slot Area = 1.20 $in^2 = 0.0083$ ft²

ENDPLATES

Circular, Diameter = 13 inches

Thickness = 0.125 inches

MATERIAL

Model - Brass

Endplates - 24ST Aluminum

BOUNDARY LAYER EQUIPMENT

Airflow ducting - 0.75 inch (internal diameter) pipe

Pressure Reservoir - 50 gallon drum

Feed Pumps - 2 Black and Decker commercial vacuum cleaners

VI. NOMENCLATURE

L = Total lift developed by airplane - 1bs

W = Gross weight of airplane - lbs

 C_L = Lift coefficient = $\frac{L}{\frac{1}{2} (\sqrt{2}S)}$

 C_D = Drag coefficient = $\frac{D}{\frac{1}{2}\ell \text{ V2s}}$

V = Flight or free stream velocity - ft/sec

e = Density of air - slugs/ft3

 \mathcal{Q}_g = Geometrical angle of attack with reference to the wing chord plane

= Angle of yaw

R = Reynolds number of flow

S = Wing area - ft2

AR = Aspect ratio of wing

MAC = Mean aerodynamic chord - ft

Q = Quantity of air removed by boundary layer suction - ft³/sec

 C_Q = Quantity flow coefficient = $\frac{Q}{VS}$

 $\delta_{\rm FN}$ = Deflection of nose flap in degrees as measured from the wing chord plane

 $\delta_{\rm F_S}$ = Deflection of slotted trailing edge flap in degrees as measured from the wing chord plane

 $\Delta P = \Delta P_1 + \Delta P_2 + \Delta P_3$

ΔP₁ = Difference between the free stream static pressure and the static pressure at the 20% wing chord - lb/ft²

 ΔP_2 = Kinetic energy lost at exit - lb/ft²

ΔP₃ = Internal pressure losses due to ducting - lb/ft²

? = Efficiency of suction pumps

- 13 -

IX. DISCUSSION

The experimental results appear in figures 4 through 81, while tables of $C_{\rm I_{max}}$ and $\Delta C_{\rm I_{max}}$ for each configuration appear on pages 34 and 35 respectively.

Since the Reynolds number effects show only a small variation in maximum lift coefficient (figures 5 to 7), Reynolds number changes have been neglected throughout this report. The value of the tunnel dynamic pressure, q, used was selected after consideration of both the Reynolds number and the suction quantity. The intentions were to be able to investigate a range of C_Q values and yet keep the maximum value within a reasonable limit*.

Increasing the suction quantity for all configurations increases the maximum lift except for a few instances with slot Δ_2 . From the results presented in figures 8 to 34, it is apparent that the forward slot is more effective in increasing the maximum lift than either slot Δ_2 or the slot combination $\Delta_1 \Delta_2^{**}$. The lift increment obtained by increasing the suction quantity is also greater for slot Δ_1 than for the other slot configurations, but decreases with increasing suction quantity. The greatest gains in lift on the basic airfoil arise from deflecting the nose flap, e.g., $C_1 = 0.250$ for a

^{*} It should be emphasized that when slot configuration $\mathcal{A}_1\mathcal{A}_2$ was used, the suction quantity removed at each slot was less than for the single slot \mathcal{A}_1 or \mathcal{A}_2 configuration. Since the static pressure at slot \mathcal{A}_1 is less than that at slot \mathcal{A}_2 , it is apparent that the suction quantity removed from each slot was not equal; a greater amount would be removed through slot \mathcal{A}_2 due to the lower pressure head. Therefore the effectiveness of slot \mathcal{A}_1 is decreased.

^{**} The application of this wing to an actual full scale airplane was kept in mind throughout this investigation so that the horsepower required and available for the boundary layer suction was kept as low as possible.

^{***} This effect is shown later in a section of cross plots (figures 64 to 72).

DISCUSSION (cont'd)

15° deflection. Deflecting the nose flap also greatly changes the angle of stall of the airfoil. Changing the suction quantity was found to have a minor effect on the stall angle. The angle of stall is also influenced to some extent by the deflection of the slotted trailing edge flap. In particular for the case where the nose flap is deflected with the slotted flap, the angle of stall actually decreases. The maximum angle of stall obtained was 23° for the SF $_{\rm N}$, 6F $_{\rm N}$ = 30°, C $_{\rm Q}$ \neq 0 configuration. For the maximum lift configuration as well as most of the high lift configurations the stall was sudden and was usually accompanied by severe buffeting. In several instances, the lift obtained with suction applied on slot Δ_2 was actually lower than the maximum lift of the basic airfoil without suction. As this condition disappeared as the suction quantity was increased, it is apparent that the lower suction quantities were insufficient to reestablish the flow over the rear of the airfoil.

Figures 35 to 43 present the effects of slot location for each basic configuration for a $C_Q = 0.0071$. In each case the location of the slot aft of the nose flap (slot A_1) proved superior to a slot located on the 70% wing chord (slot A_2). It also appears that the slot combination A_1A_2 is superior to the slot A_2 . However the figures demonstrate that slot A_2 is better than no slot at all. Slot A_1 gives maximum lift coefficient increments of from 0.1 for the "flaps up" configuration to 0.55 for the SFNFs, $S_{FN} = S_{FS} = 30^{\circ}$ configuration.

Figures 44 to 59 present the flap effectiveness for the nose flap, slotted trailing edge flap, and their combinations for C_Q =0.0071 and various slot configurations. The nose flap results indicate:

DISCUSSION (cont'a)

- 1. the greater the nose flap deflection, the greater the lift
- 2. slot A_1 increases the lift increments obtained for a given flap deflection more than either slot A_2 or slot A_1A_2
- 3. the angle of stall increases with nose flap deflection but remains relatively constant as the slot location varies

The slotted flap results indicate:

- 1. there is an optimum slotted flap deflection, after which the maximum lift decreases for increasing flap deflection
- 2. slot A_1 increases the lift obtained for a given flap deflection more than either slot A_2 or slot A_1A_2
- 3. the angle of stall decreases for a slotted flap deflection

The slotted flap effectiveness, for $\delta_{F_N} = 15^{\circ}$, indicates the same conditions as does the previous case where $\delta_{F_N} = 0^{\circ}$. For the slotted flap effectiveness where the nose flap is deflected 30° , the characteristics of the nose flap influence the slotted flap such that:

- 1. for $C_Q = 0$, the lift obtained with the slotted flap at 60° is greater than the lift obtained with the flap at 30°
- 2. slot A_1 increases the lift obtained for a given flap deflection more than either slot A_1 or slot A_1A_2

^{*} This effect is clearly shown in figures 60 to 63

DISCUSSION (cont'd)

3. the angle of stall decreases for slot A_1 and slot A_1A_2 , and increases for slot A_2

Figures 60 to 63 show the variation of the maximum lift coefficient with flap deflection for the maximum suction quantity ($C_Q = 0.0071$) and for the various slot configurations. For the basic airfoil with no suction, figure 60 indicates that the most profitable configuration is $\delta_{FN} = 30^{\circ}$, $\delta_{FS} = 60^{\circ}$. From the curves it is apparent that more lift could have been obtained by deflecting the nose flap past 30° . For the slot Δ_1 configuration, figure 61, the optimum configuration was $\delta_{FN} = \delta_{FS} = 30^{\circ}$. The plot also indicates that:

- a higher lift could be obtained by deflecting the nose flap to a greater angle
- 2. there exists an optimum slotted flap deflection past which the lift decreases with increasing flap deflection

These same results are apparent in the slot I_1I_2 configuration, figure 63, however on figure 62, slot I_2 , the optimum configuration again becomes $\delta_{FN} = 30^{\circ}$, $\delta_{FS} = 60^{\circ}$ as in the "suction off" condition. Future investigations with the airfoil should center around increasing the nose flap angle and slotted flap angle past 30° in increments to determine this optimum flap configuration and obtain a greater maximum lift.

In the last group of figures (figures 64 to 72), the variation of the lift with suction quantity (slot configuration as parameter) for angles below the stall angle are presented for each model configuration.

DISCUSSION (cont'd)

The general result that these plots indicate is that by increasing the suction quantity above the maximum used, the lift increase obtained would be small and undoubtedly insufficient to warrant the increase in the horsepower for the suction. Thus future study with this particular airfoil should center around flap deflections and possibly suction distribution, but not suction quantity.

On page 36, the horsepower required to operate this boundary layer control on a full scale airplane is estimated. The formula used is $hp = \frac{Q(\Delta P)}{550 \, ?}$, where ΔP is the sum of the losses and pressure head chargeable to the suction pump. Some of the values have been assumed due insufficient data while others have been obtained from references (see particularly reference 12). The value obtained was $\frac{54.6}{?}$, a value considered reasonable and not too demanding upon an airplane power plant.

The final group of figures present the results of the tuft investigations conducted on the optimum model configurations. The main indications are that flow separation begins at the leading edge and progresses rearward. Suction and flap deflection only tend to delay the leading edge separation to higher angles of attack.

X. SUMMARY OF RESULTS

This thesis presents results of an investigation of boundary layer suction as a means of increasing the maximum lift coefficient of a double-wedge supersonic airfoil operating at low subsonic speeds.

The model used was a 10% thick, double-wedge airfoil located between endplates with spanwise suction slots at the 20% and 70% wing chord. Both a 20% chord nose flap and a 20% chord slotted trailing edge flap were incorporated on the model. Boundary layer suction was applied to the forward slot, to the rear slot, and to both simultaneously, for all possible model configurations. The greatest increase in lift was obtained with both flaps deflected 30° and with maximum suction ($C_Q = 0.0071$) applied to the forward slot only ($C_{L_{max}} = 2.149$). In all cases the greatest increments in lift were obtained with the nose flap and front slot combinations. For the slotted trailing edge flap, there appeared to be an optimum deflection (between 30° and 60°) past which the lift would decrease. The rear slot in most instances proved to be much less effective in increasing the lift, than the front slot.

XIV. HORSEPOWER COMPUTATIONS

hp =
$$\frac{Q(\Delta P)}{5507}$$
, where $\Delta P = \Delta P_1 + \Delta P_2 + \Delta P_3$

Assume the following dimensional data of a full scale airplane:

W = Weight = 10,000 lbs
S = Wing Area = 440 ft²
$$C_{L_{max}}$$
 = 2.100
MAC = 9.5 ft
AR = Aspect Ratio = 5.5 ft C_{Q} = 0.0071
 ℓ = 0.002378 slugs/ft³

For level flight: $L = W = \frac{1}{2} \rho V^2 C_T S$

or
$$V = \begin{bmatrix} 2W \\ 0C_LS \end{bmatrix}^{\frac{1}{2}} = \begin{bmatrix} 20,000 \\ .002378x2.1x440 \end{bmatrix}^{\frac{1}{2}} = 95.5 \text{ ft/sec}$$

$$Q = C_0 VS = 0.0071 \times 95.5 \times 440 = 298 \text{ ft}^3/\text{sec}$$

$$\Delta P_1 = p(\text{free stream}) - p (20\% \text{ wing chord})^* = 1.50 x q$$

= 1.50 x 40 = 60 lb/ft²

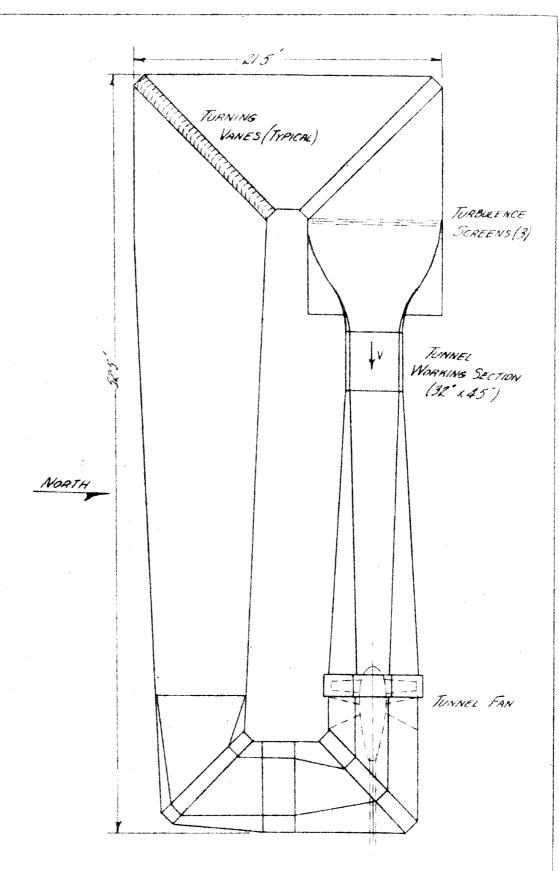

$$\Delta P_2 = \frac{e}{2} V^2$$
 (Assuming boundary layer air leaves with free stream velocity) = $\frac{e}{2}$ (95.5)² = 10.84 lb/ft²

$$\Delta P_3 = 30 \text{ lb/ft}^2 **$$

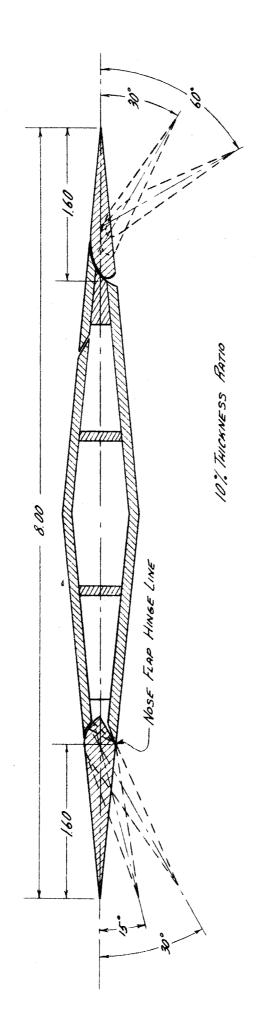

$$\Delta P = \Delta P_1 + \Delta P_2 + \Delta P_3 = 60 + 10.84 + 30 = 100.84$$

^{*} The value of the static pressure at the 20% wing chord was obtained from Reference 12

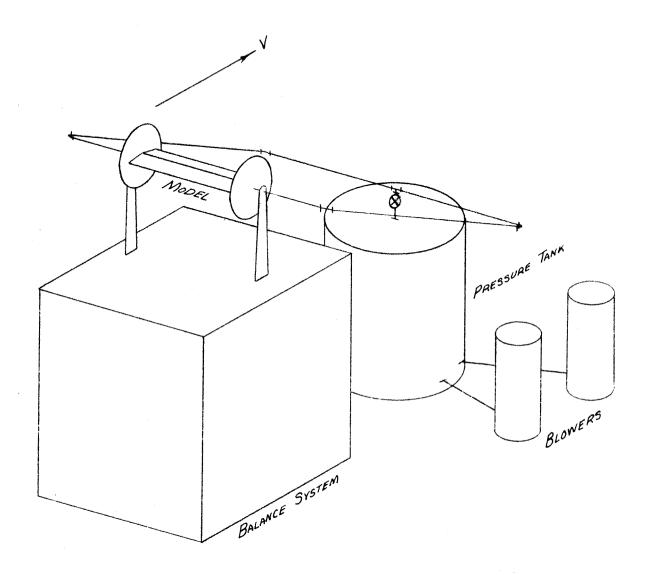

^{**} This value is assumen and is relatively high, however, it allows a "dirty" air duct configuration that might be necessary in a military airplane
