I would like to thank my advisor, Tom Heaton. Throughout my time at Caltech, he was continuously jovial, and gave me great encouragement. He has always been overly generous with his time, and I have learnt much from our frequent discussions.

I would like to acknowledge Jascha Polet and David Johnson from SeismoLab, who taught me a lot about the hardware and software issues, helped set up countless experiments, and were always helpful with data analysis and recovery. I also would like to thank Arnie Acosta and Erdal Safak for their help with obtaining data from the USGS array at Millikan Library. Mr. Isamu Yokoi from Tokyo-Sokushin was also extremely helpful with all issues that arose with the VSE sensors. I would like to thank IRIS for purchasing the VSE-355G2 sensor.

The faculty and students of Civil Engineering also provided great support. In particular Brad Aagaard for the brains, Andy for the sharing the misery at 2am all first and second years long, Swami, Javier and Case for the laughs. And especially Case for the extensive proof-reading.

My mother-in-law, Maria Cua, helped out with minding Peete, letting us get some work done.

My parents, Peter and Margaret, so far away for these past years, have yet managed to share much of my Caltech experience, and helped me make it to the end.

But after everyone has gone home, Peete and Georgie were always there, and allowed me to too often not go home myself. Thanks for your patience and love. For what its worth, this is for both of you.

Abstract

The recording of ground motions is a fundamental part of both seismology and earthquake engineering. The current state-of-the-art 24-bit continuously recording seismic station is described, with particular attention to the frequency range and dynamic range of the seismic sensors typically installed. An alternative method of recording the strong-motions would be to deploy a velocity sensor rather than an accelerometer. This instrument has the required ability to measure the strongest earth motions, with enhanced long period sensitivity.

An existing strong motion velocity sensor from Japan was tested for potential use in US seismic networks. It was found to be incapable of recording strong motions typically observed in the near field of even moderate earthquakes. The instrument was widely deployed near the M8.3 Sept 2003 Tokachi-Oki earthquake. The dataset corroborated our laboratory observations of low velocity saturations. The dataset also served to show all inertial sensors are equally sensitive to tilting, which is widespread in large earthquakes. High-rate GPS data is also recorded during the event. Co-locating high-rate GPS with strong motion sensors is suggested to be currently the optimal method by which the complete and unambiguous deformation field at a station can be recorded.

A new application of the modern seismic station is to locate them inside structures. A test station on the 9th floor of Millikan Library is analysed. The continuous data-stream facilitates analysis of the building response to ambient weather, forced vibration tests, and small earthquakes that have occurred during its lifetime. The structure's natural frequencies are shown to be sensitive not only to earthquake excitation, but rainfall, temperature and wind. This has important implications on structural health monitoring, which assumes the natural frequencies of a structure do not vary significantly unless there is structural damage.

Moderate to small earthquakes are now regularly recorded by dense, high dynamic range networks. This enhanced recording of the earthquake and its aftershock sequences makes possible the development of a Green's Function deconvolution approach for determining rupture parameters.
