Summary

The extensive use of reinforced duralumin sheet in aircraft construction makes it desirable to know the behaviour of such structures under load. This paper deals principally with the experimental results obtained by testing a large number of reinforced panels of various lengths under direct compression.

The main purpose of the investigation was to determine the ultimate stresses in the reinforcing members, which in this case were bulb-angles of a size commonly used in aircraft construction. It was, however, felt that it would be desirable to obtain as much information from the tests as possible. Consequently the stresses in the bulb-angles were measured at intermediate loads for a number of panels. From this data it was possible to determine that portion of the total load carried by either the skin or the bulb-angles throughout the entire range of load.

Acknowledgment

The author wishes to express his appreciation to Dr. E. F. Sechler for his helpful suggestions in the preparation of this paper, and also to Mr. Irving Ashkenas for his aid in testing and calculating results. Gratitude is also expressed to the National Advisory Committee for Aeronautics for providing the necessary funds, to the Douglas Aircraft Company who furnished a number of the stiffener sections, and the North American Aviation Company for their cooperation in building the test specimens.

Introduction

A systematic study of the behaviour of bulb angles under load when used as reinforcing members in thin sheet metal construction was undertaken at the California Institute of Technology during the Institute year 1936-37, see reference I. The work has been continued during the current year and this report deals primarily with the progress which has been made.

The behaviour of a bulb angle stiffener, under load, when attached to a sheet is rather complex and it becomes necessary to consider the effect of the attached sheet on the stiffener and also the effect of the stiffener on the sheet. The sheet stringer combination should be considered as a unit since neither act independently and can only be separated when the interaction is definitely known. It is therefore necessary to know what the variation of stress in the stiffener is with increasing applied loads and for various skin stresses. Consequently, the stiffener stresses were measured for a large number of panels throughout the complete range of the applied load. By averaging the strains obtained from the extensometer readings, an average load strain curve was obtained for each panel.

To obtain the stress distribution in the skin the wave pattern of the buckled sheet was obtained. Knowing the wave pattern it is possible to calculate the compressive stress due to the applied load. From the stress strain curves were then calculated the stiffener loads, the load carried by the skin and the effective width of skin acting with each stiffener.

Test Specimens

All specimens were made by the North American Aviation Company.

In order to obtain square and parallel ends, all panel ends were carefully milled in a milling machine. The ends were kept parallel to within .0010 inch.

The panel lengths were so chosen as to cover the complete range of bulkhead spacings which may be encountered in design practice and furthermore the lengths were such as to cover the normal short column range and in certain instances, depending on the dimensions of the bulb angle, to reach the normal long column range.

The number of stiffeners was varied in order to investigate the effect, if any, of the number of stiffeners on the ultimate stiffener stresses.

The first eighteen panels tested consisted of .020-24 ST Alclad skin with bulb angle #10266, see reference I and page 52 of this report. The panel lengths were 3, $5\frac{1}{2}$ 11, $16\frac{1}{2}$, 22 and $27\frac{1}{2}$ inches and the number of stiffeners, two, three and four. For all panels, the stiffener spacing was taken as 5 inches and the rivet spacing as 0.75 inches. The rivet spacing was so chosen that premature buckling of the skin between rivets would not occur for either the thin or thick sheet. In each panel the sheet extended $2\frac{1}{2}$ inches beyond each outboard stiffener, that is, the total width of the panel with two stiffeners was 10 inches; with three stiffeners, 15 inches; and 4 stiffeners 20 inches.

Upon completing the first eighteen panels it was decided that,

in the future, duplicate panels were to be tested in order to minimize experimental scatter. The second series of test consisted of 36 panels with .040 skin - 24 S T Alclad using bulb angle #8476, see reference I and page 52 of this report. The number of stiffeners was again two, three and four, duplicate specimens of the various combinations were made. It was found that in general the dimensions of the bulb angle varied considerably from those specified by the manufacturer. To determine an area, which would represent the average area of the stiffeners, a long bulb angle section was weighed and the area computed using an average density of .010 lbs / cubic inch.

Test Apparatus and Testing Procedure

All specimens were tested flat ended in a standard 150,000 lb. Olsen testing machine.

To insure an even load distribution over the panel, two special face plates were made. The surfaces were kept parallel to within .001 of an inch. The two surface plates were placed between the heads of the testing machine and the test panel mounted between the two face plates. A small increment of load was applied to hold the panel in position while Huggenberger extensometers were mounted on each stiffener as shown in figure M . The free edges of the panel were supported by means of slotted steel tubes, 3/4 0. D. x .093, a clearance of approximately 1/8" being allowed at each end of the panel. It was felt that clamping the tubes to the sheet would give too great a rigidity to the free edges; hence the free edges were merely inserted in the slotted tubes. The clearance between the slot and the sheet was about .010 inch, thus allowing the edge to buckle slightly. This condition probably more nearly approximates the condition at the stiffener than that which would be obtained if the edges were rigidly clamped.

Upon applying the load it was found that, notwithstanding the care exercised in milling the ends of the test panel and using the face plates as described, the load distribution over the width of the panel was found to be uneven. This was due to the non-parallel motion of the movable head of the test machine with reference to the fixed base. This necessitated shimming of the

face plates until the extensometer readings indicated an even load distribution. To measure the overall deflection of the test panel four Ames dial gages were mounted between the moveable head and the fixed base of the test machine. The dial gages were placed two at each edge of the panel one on each side. The average reading of the four gages would indicate the overall deflection of the centre of the panel.

It was further desired to obtain the complete wave pattern, between stiffeners, of the buckled sheet.

- (1) A slider which can be moved in a vertical direction.
- (2) A square tube which guides the slider.
- (3) A rack which moves against the panel and runs on a half inch diameter gear which is housed in the slider.
- (4) A rack which traces the profile of the buckled sheet on a sheet of graph paper wrapped around a hexagonal drum. This rack receives its motion from a $2\frac{1}{2}$ diameter gear which runs on the same shaft as the $\frac{1}{2}$ diameter gear. The two gears are rigidly connected. The purpose of the gear system is to obtain a five times magnification of the wave amplitude.
- (5) A hexagonal drum on which the sheet profile is traced and which revolves around a shaft which is rigidly connected to the square tube. By turning the drum through 60 degrees a new curve can be drawn.

(6) The frame which holds the tracing mechanism in position and also provides an upper and lower guiding slot for moving the entire tracing mechanism in a horizontal direction.

The shaft on which the two gears are mounted is turned by a small coiled clock spring thus causing the rack, which runs against the panel, to follow the contour of the sheet and at the same time eliminating any slack which may exist in the gear system, as the pressure is always on one side of the gear teeth.

The operation is as follows:

The lower base of the frame is clamped to the fixed base of the testing machine. The tracing mechanism can then be moved to any desired position between stiffeners; and by moving the slider up or down the sheet profile is automatically traced on the drum.

The loading was applied in 12 to 15 increments, extensometer and dial gage readings being recorded for each increment of load. The extensometers were removed near the failing load of the panel and the loading continued until failure, i. e. until the load decreased with an increase in overall deflection. A number of panels were merely tested to failure, i. e. without obtaining the stiffener stresses or overall deflections.

Experimental Results

The stiffener stress up to the proportional limit, can be obtained directly from the extensometer readings by means of the equation:

T. = KEE

where \$\int_{37} = \text{stiffener stress in lbs./ sq. inch.}\$

K = Extensometer constant

= unit strain in inches / inch.

E Youngs Modulus

To obtain the stiffener stresses above the proportional limit, two $2\frac{1}{2}$ " bulb angle specimens where tested in compression and standard stress strain curves obtained, see fig. II, page 3/. Using the strain reading for the panel, the corresponding stress could be obtained from the stress strain curves. Since the two stress strain curves deviated slightly an average value was used. A tension stress strain curve plotted on page 3/, fig. II, indicates that a tension stress strain curve cannot be used since the proportional limit in compression is much lower.

The load carried by the skin is given by the equation:

And the effective width acting with each stiffener by:

$$W_{e} = \frac{P_{sk}}{2(n+k)t} = \frac{P_{sk}}{2(n+k)t} \frac{P_{sk}}{P_{sk}}$$

$$P = \text{Total applied load in lbs.}$$
3

Where:

We = Effective width of skin acting with each stiffener. (Ref. II)

7 = Number of stiffeners

Asr = Stiffener area

t = Skin thickness

K = The ratio between the load carried by each

effective width of skin and the additional load carried by the skin due to the free

Evaluation of K.

The effect of the tubes over the free edge of the panel is to stiffen the sheet between the stiffener and the tube, effectively this means, that the panel width is $2\frac{1}{2}$ inches rather than 5 inches. Since the panel width is decreased the critical buckling stress of the sheet is increased and the skin between the tube and the stiffener will be acting at a higher average stress than the skin between two bulb angles. Since, the effective width is proportional to the load carried by the skin, the ratio of the additional load carried by the sheet to that which would normally be carried if the panel were continuous can be given by the equation:

edges support.

Where: Were Effective width between tube and stiffener

We - Effective width between stiffeners.

The effective width will be calculated by the equation given in reference III.

 $W_e = \frac{b}{2} \sqrt{\frac{V_{c_v}}{V_{s_T}}} \qquad \boxed{S}$

Where: $\sqrt{l_{e_{a}}}$ = Critical buckling stress of the sheet

Os, stiffener stress

b = Stiffener spacing.

Assuming the tube to give the same support to the skin as the stiffener and if,

Uc. ' = Critical buckling stress of the sheet between stiffener and tube.

Uc = Critical buckling stress of the sheet between the stiffeners.

b' = Spacing between the stiffener and the tube
b = Stiffener spacing

Then
$$W_c = \frac{5}{2} \sqrt[3]{\frac{C_{c,r}}{V_{s,r}}}$$

Noting that $\frac{b}{2} = b$ and substituting (6) and (7) in (4) gives: $K = \sqrt[3]{\frac{\pi}{4\pi}} - / 8$

It should be noted that for all values of 5,46, K:0 since

For all values of $\sqrt{s_7} > \sqrt{c_7}$, K = constant.

The critical buckling stress of a panel simply supported on 4 sides is given by:

Where M = Poisson's Ratio

For t = .090", b . 5", M = .3 , E = 10" #/sq. Inch

$$\int_{\text{CY}} = \frac{\pi^2 x_{10}^2 \left(.040\right)^2}{3(1-.3^2)} = \frac{2,320}{5} \frac{\#}{\text{sg. Inch.}}$$

For t = . 040", b = 2.5", M = . 3, E = 10" / sq. inch.

$$\int_{c_7} = \frac{\pi^2 x_{10}^2}{3(l-3^2)} \left(\frac{040}{2.5} \right)^2 = \frac{9,270}{3(1-3^2)} \left(\frac{9}{2.5} \right)^2 = \frac{9,270}{3} \left(\frac{1}{3} \right)^4$$

A plot of K against \mathcal{L}_{37} is shown on page 26.

The stress distribution across the sheet, between two stiffeners and between the outboard stiffener and the tube, was obtained experimentally for a stiffener stress of 19,500 #/ sq. inch. and is shown in figure \mathcal{I} page $\mathbf{Z}/$.

It can be seen from the figure that

$$K = \frac{B}{A}$$

Where A = The area under the stress curve "a"

 \mathcal{B} = The area between the stress curve "a" and "b"

The areas where found by plenimeter to be

$$A = 24.06$$
 , $B = 15.1$
 $K = \frac{15.1}{24.06} = 0.627$

The value of K computed by equation (8) was 0.586

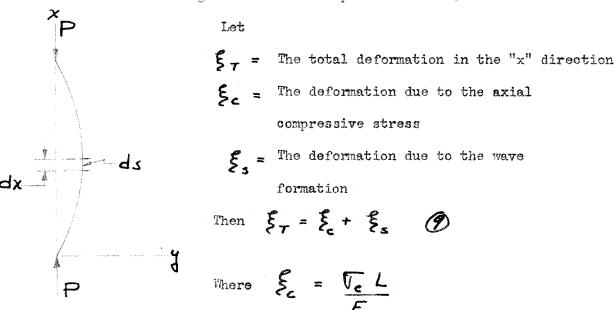

the difference is 7%. Knowing the value of K as a function of the stiffener stress the average effective width was computed using the stiffener stresses obtained from the load strain curves which are shown on pages 32 to 5%. The results are shown on pages 28, 29, and 30, where is plotted against the stiffener stress. The experimental scatter for the three and four stiffener panels is quite reasonable considering the fact that the variation in the bulb angle dimensions as obtained from the factory will vary as much as 10%. The experimental scatter for the two stiffener panels is for some unknown reason much larger than for the three and four stiffener panels.

The ratio was plotted against the dimensionless parameter $\Lambda = \sqrt{\frac{E}{S_T}} \frac{t}{L}$ see reference II. The values of we and S_T were read from the faired curves on pages 28 and 29. The results are plotted on page 25, the curves A and B given in reference II are also drawn on the same page. The suggestion in reference II, that the curve in the transition region between A and B be considered as a straight line is shown by the experimental results to be a good approximation. The experimental results indicate that when we is

that when is plotted against \(\) it is probable that a family of curves will be obtained one for each sheet thickness. Stresses in the sheet:

An element of thin sheet subjected to an axial compressive load will deform in the axial direction an amount proportional to

L until buckling takes place. Beyond the buckling load the deformation will be a function of the axial compressive stress in the sheet and the magnitude of the compression waves.

If "ds" is the length of an element of buckled sheet and the corresponding element of chord is "dx" then the displacement due to bending in the "x" direction is

From which

$$d\xi_{s} = dx \sqrt{1+|dy|^{2}} - dx \approx \frac{1}{2} \frac{|dy|^{2}}{dx}$$

$$(REF. IV)$$

$$\xi_{s} = \frac{1}{2} \int_{0}^{1} \frac{dy}{dx} dx$$

may be obtained experimentally by measuring the overall
deflection of the panel, or for the case in which the stiffener is

not buckled.

$$\xi_T = \sqrt{\frac{1}{S_T}} L$$

Substituting in Equation (9) gives:

From which

Where:

 σ_{c} = Axial compressive stress in the sheet

∠ = Panel length under consideration

Es = Youngs modulus for the sheet

Est = Youngs modulus for the stiffener

For the case in which $\mathcal{L}_{s} = \mathcal{L}_{sr}$ equation (10) reduces to

It was found from the wave pattern obtained for the buckled skin that a close approximation could be obtained by taking

Where A = Amplitude in inches (obtained experimentally)
Substituting in Eq. (II) gives:

$$T_c = T_{s_T} - \frac{\pi^2 E_s R^2}{4L^2}$$

A disadvantage of Eq (11) is that in general both terms on the right hand side are large and the difference determines a small quantity. However, with a reasonable amount of care satisfactory results can be obtained. The stress distribution for two duplicate panels is shown on page 27.

Stiffener stresses.

The ultimate stiffener stresses were computed by the formula.

The procedure being as follows:

A value of ∇_{37} is assumed and the corresponding value of obtained from curve A, reference II. This procedure is repeated until the above equation is satisfied. The Ultimate stiffener stresses are plotted against $\frac{4}{3}$ as shown on page $\frac{2}{3}$ to $\frac{24}{3}$. The value of ρ is that of the stiffener plus the effective width.

Conclusions

The present data is not sufficient to draw any definite conclusions; however by observing the manner in which the bulb angle stiffeners fail it seems that failure may occur by:

- (a) local buckling of the outstanding leg.
- (b) Twisting of the angle section.
- (c) Euler column failure.

Local buckling will occur if the outstanding leg is wide as in this case the torsional stiffness of the section is comparatively large and the critical local buckling stress of the stiffener is lower than the critical stress for a twisting failure.

Failure by twisting will occur if the outstanding leg is narrow, in this case the torsional stiffness is low and the twisting moment introduced by the skin at the stiffener cause the angle to roll. As soon a twisting takes place, torsion-bending stresses are produced causing failure of the section at a lower stress than the critical local buckling stress.

Euler failure will occur for values of 4 large enough to fall in the Euler range.

It was observed, from the profiles obtained for the buckled skin, that the 27 inch panels with .040 skin will buckle in 8 half waves and the 21 inch panels in 6 half waves. The half wave is therefore approximately $3\frac{1}{2}$ inches, whereas theoretically the half wave length should correspond to the stiffener spacing, namely 5 inches. The same phenomena was observed for the .020 skin. This difference between the theoretical and actual wave length may be a

contributing factor to the difference which exist between the effective width calculated from existing theory and that determined experimentally.
