ACKNOWLEDGEMENT

The author is indebted to Mr. H.L. Wheeler and his staff of the Materials Section, Jet Propulsion Laboratory for guidance in all phases of the preparation of this thesis. Grateful acknowledgement for help in the fabrication of the apparatus described herein, is made to Mr. Ed. Sechler and his colleagues. Mr. Leo Zwell lent extensive assistance in making the numerous and tedious readings.

ABSTRACT

The techniques of powder metallurgy have produced porous variations of the metals copper, steel and nickel. The proposed application of these porous metals in the sweat-cooling of jet propulsion engines demands an exact knowledge of their thermal as well as their physical properties.

This thesis presents an experimental determination of the thermal conductivity of copper as a function of porosity, and an insight into the way this conductivity depends on temperature.

The experiments were performed on a simplified version of the apparatus used by the Bureau of Standards for solid metals. Four copper specimens varying in porosity from 22 to 42 per cent were measured. The results obtained are consistent with those predicted by other investigators from entirely different considerations.

The results are summarized in two graphs. The first shows temperature versus thermal conductivity. The second gives thermal conductivity versus porosity. It is shown that porosity largely determines thermal conductivity while temperature is distinctly a second-order influence. An analytical expression for the variation of thermal conductivity with porosity is introduced, and general agreement with the experimental results is noted.

PART I

INTRODUCTION AND SUMMARY

The thermal conductivity of porous metals is of considerable practical interest in the technique of sweat cooling. For this reason an experimental determination of the thermal conductivity of several porous metals was begun at Jet Propulsion Laboratory. Because of limitations of the equipment, only porous copper has been tested up to this time.

This study was performed on an apparatus of the type used by Van Dusen (Cf. Ref. 1) for measuring the same property in solid metals. The method was to compare two specimens, one of known conductivity, through which heat flows in series. The specimens were placed in an apparatus hereafter called the "conductometer."

Axial temperature gradients in two cylindrical rods placed firmly end to end were measured under conditions approaching thermal equilibrium. When a steady state had been attained, the heat flux, assuming no radial losses, was the same in both bars. The conductivity at any point in either bar was inversely proportional to the temperature gradient at that point. If the absolute value of the conductivity of the metal of one bar was known at some temperature within the experimental range, the thermal conductivity of the other bar could be calculated for all points at which the temperature gradient had been determined.

The experiment involved testing four copper specimens of 22, 28, 39, and 42 per cent porosities, and in addition, one wrought copper specimen, for the purpose of calibrating heat losses in the conductometer.

PART II

DESCRIPTION OF THE EQUIPMENT

Elaborate refinement of the apparatus to obtain great precision was not attempted. Figure 18 illustrates the conductometer disassembled, while Figure 19 shows the conductometer enclosed by a transite tube, or shield. This tube serves to contain powdered asbestos lagging. Referring to Figure 18, it is seen that heat from a controlled source passes through a six-inch copper specimen, then through a three-inch pure iron standard of identical cross section. A diameter of one-half inch was chosen for both standard and specimen. No attempt was made to solder the two rods since solder would flow into the spaces in the matrix of the porous copper. The lower end of the copper specimen rested on an iron cylinder with a truncated conical top. This cylinder served to guide the heat into the specimen (Cf. Fig. 20).

The pure iron standard is an integral part of the heat sink, in which cooling channels were machined. However, the use of circulating water was abandoned after it was observed that adequate temperature gradients were being obtained with no coolant flow. Six number 28 chromel-alumel thermocouples were fastened to the copper specimen, and five to the standard, in the following manner: the thermocouple wires were first welded together, then the bead was inserted in a shallow .040 inch diameter hole, and peened to insure good contact. The thermocouples were an inch apart on the specimens, and half an inch apart on the standard. The twenty-two thermocouple leads were passed to a Jones

strip which was in turn connected to an eleven-position rotary selector switch. Temperatures were read directly on a model 8370 Leeds and Northrup potentiometer which was positioned on the table to the left of the rotary switch.

A short comparison between the present conductometer and that used by Van Dusen at the Bureau of Standards might well be made. The Van Dusen equipment differed chiefly in the number of refinements.

(1) In place of the transite tube there was used a tube which was stainless steel where it paralleled the specimen and nickel where it paralleled the standard. The temperature gradients along this metal tube could be matched to the temperature gradients in the specimen and standard, thus preventing heat transfer from the specimens to the outside air.

(2) A heat sink using water at constant temperature was provided.

(3) Although the Van Dusen equipment was rapidly brought up to temperature on alternating current, thermal equilibrium was maintained on a constant direct current source of electricity. The present conductometer used only the laboratory power source, which fluctuates because of the demands of other projects at the laboratory.

PART III
METHOD OF ANALYSIS

The method of analysis, briefly outlined, was as follows:

(1) The first step was to calibrate the conductometer for radial heat losses using a wrought copper specimen of known conductivity. The purpose of this calibration is to correct the slopes of the curves in Figure 3. The curves to be corrected are labeled T_{obs} , observed temperature. Absolute temperature, in the computation of thermal conductivity, is not significant; temperature gradient, °F per inch, is the important factor.

The lines labeled T_{cal} in Figure 3 have the correct slope for the particular value of junction temperature used as a reference point. The reader should not attempt to correlate the new values of absolute temperature at each thermocouple with the observed values. These new values are arbitrary and depend on which thermocouple is used as a point of reference. The amount of heat loss at each thermocouple on the standard was assumed negligible, since those thermocouples are relatively cool.

Two sets of temperature gradients resulted from this method, one determined from the potentiometer readings, and the second computed from the known thermal conductivity of the wrought copper. By comparing the first group of readings with the second group, Table I and Figure 3 were constructed. The corrections gleaned from Table I and Figure 3 were then consolidated on the conductometer calibration chart, Figure 4. The calibration chart gives a corrected curve for each run in Figures 5, 6, 7, and 8. Of each pair of lines, these lines are

to the left and are labeled T_{cal} .

(2) Another set of graphs, Figures 9 through 14, was drawn giving temperature gradient versus temperature. This resulted in one curve for each specimen.

(3) The final computations, Tables 8 and 9, involved the use of Figures 1 and 2, and Figures 9 through 14 to solve the basic equation

$$K_c \left[\frac{\Delta T}{\Delta l} \right]_c = K_s \left[\frac{\Delta T}{\Delta l} \right]_s$$

for the thermal conductivity of porous copper

$$K_c = K_s \frac{\left[\frac{\Delta T}{\Delta l} \right]_s}{\left[\frac{\Delta T}{\Delta l} \right]_c}$$

In this equation,

K_s is the thermal conductivity of the iron standard. Thermal conductivity is defined as the time rate of transfer of heat by conduction, through unit thickness, across unit area for unit difference of temperature. In this experiment, the units are: $\text{BTU sec}^{-1} \frac{\text{in}}{\text{in}^2} \text{ } ^\circ\text{F}^{-1}$ or $\text{BTU sec}^{-1} \text{in}^{-1} \text{ } ^\circ\text{F}^{-1}$. These values are conveniently plotted in Figure 1.

$\left[\frac{\Delta T}{\Delta l} \right]_s$ is the temperature gradient of the iron standard, and is obtained from Figure 9

$\left[\frac{\Delta T}{\Delta l} \right]_c$ is the temperature gradient of the porous copper specimen, and is obtained from Figures 11 through 14.

PART IV
EXPERIMENTAL PROCEDURE

The experimental procedure for both the wrought copper calibration rod and for the porous copper specimens (Cf. Ref. 2) was identical. The specimen was placed in the conductometer (Cf. Figure 18) between the heating coil and the standard, insuring the best possible contact at all points. The middle section of the transite tube was replaced (Cf. Figure 19), powdered asbestos was poured in, and the top section of the tube was positioned. The 110 volt power-line was connected through a micromax to the heating coil. The rheostat on the micromax was convenient for controlling the power input to the heating coil. The micromax indicated the temperature of the hottest thermocouple at all times, but the temperature controlling facilities of the micromax were not used after it was found that the switching on and off of the power prevented the conductometer from reaching thermal equilibrium.

Four hours were allowed for the system to reach thermal equilibrium. Actual thermal equilibrium was never attained because the source of power was under the influence of a variable line voltage caused by the demands of other projects at the laboratory. At the end of four hours two sets of readings were taken about fifteen minutes apart, or until the temperature drift became less than 5°F over the fifteen minute period. At this time, the thermocouples were read from number one through number eleven and back again. The average temperature for each thermocouple was recorded.

In practice, runs were controlled from the hottest thermocouple, and, during one installation, six runs starting at 400, 550, 700, 850, 1000 and 1150°F would be made.

In Figures 3, 5, 6, 7, and 8 there will be noticed a discontinuity at the interface or junction between the specimen and the standard. This is merely due to high thermal resistance between the two rods, since they are not soldered. However, each temperature curve above the junction corresponds to one below.

The wrought copper test rod was fabricated from electrolytic copper, the purest commercially available, and the value of thermal conductivity for this type of copper was taken from Reference 1.

PART V
RESULTS OF EXPERIMENTS

The results of the experiments may be conveniently divided into two parts; the calibration tests, and the tests on the porous specimens.

The results of the calibration tests, Table I, conducted on a wrought copper specimen were transferred to the graph, Figure 3. The lines labeled T_{obs} , observed temperature, resulted from the potentiometer readings whereas the lines labeled T_{cal} , calibrated temperature, were calibrated from the known thermal conductivity of wrought copper, as in Table I. The necessary corrections are summarized in Figure 4, the conductometer calibration chart.

The second part of the experiment involved calibrating the observed readings made on the porous copper specimens. Both the observed and calibrated temperatures are plotted in Figures 5, 6, 7, and 8.

PART VI
ANALYSIS OF RESULTS

The basic law governing heat flow in the steady state is

$$q = KA \frac{dT}{dl} \quad \text{where}$$

q is the quantity of heat in BTU

K is a proportionality constant called the thermal conductivity, and is a characteristic property of the solid through which the heat is flowing, in BTU sec⁻¹ in⁻¹ °F⁻¹.

A is the area through which the heat is flowing, in square inches.

$\frac{dT}{dl}$ is the temperature gradient at a given point in the body under consideration.

If the area is taken as unity, the law becomes, $q = K \frac{dT}{dl}$.

Two features of this law are worthy of special note. First, the thermal conductivity is, by definition, merely a proportionality constant valid for a particular body under a particular set of conditions. Secondly, the basic relation involves only the temperature gradient, and not temperature directly.

The basic law may also be written

$$K_1 \left(\frac{dT}{dl} \right)_1 = K_2 \left(\frac{dT}{dl} \right)_2$$

Within experimental limits, the temperature gradient varies so slowly with distance along the specimen that no appreciable error is introduced by taking finite lengths as large as one

inch. Hence the basic law can be written in the following manner, which was the form used for computation

$$K_1 \left[\frac{\Delta T}{\Delta l} \right]_1 = K_2 \left[\frac{\Delta T}{\Delta l} \right]_2$$

Using this form the computation of the thermal conductivity of porous copper was made as follows.

Since temperature gradients as a function of temperature could not be read directly from Figures 3, 5, 6, 7, and 8, separate graphs of these two functions were drawn. They are presented in Figures 9 through 14, where the temperature gradients are given as functions of the junction temperature, T_j . There is significant scatter in Figure 13, for a specimen of 39 per cent porosity, but Figure 14, for a specimen of 42 per cent porosity exhibits more consistency.

To obtain the thermal conductivity of porous copper for any porosity tested, it was necessary to solve the basic equation for K_c :

$$K_c = K_s \frac{\left[\frac{\Delta T}{\Delta l} \right]_s}{\left[\frac{\Delta T}{\Delta l} \right]_c} \quad \text{where}$$

K_c is the thermal conductivity of the porous copper specimen, $\text{BTU sec}^{-1} \text{ in}^{-1} \text{ } ^\circ\text{F}^{-1}$.

K_s is the same property for the iron standard and was obtained from Figure 1.

$\left[\frac{\Delta T}{\Delta l} \right]_s$ is the temperature gradient for the iron standard and was obtained from Figure 9.

$\left[\frac{\Delta T}{\Delta l} \right]_c$ is the temperature gradient for the porous copper

specimen and was obtained from one of the Figures 11,12, 13, or 14.

Figure 10 is a presentation, in graphical form of temperature gradient versus junction temperature for the wrought copper specimen. Here the temperature gradients were first calculated from the known conductivity of wrought copper, then read directly from the graph, Figure 3. The agreement is good.

The results of the above computations were plotted in two graphs. Figure 15 presents temperature versus thermal conductivity with porosity as the parameter. Figure 16 presents thermal conductivity versus porosity with temperature as the parameter. The temperature influence was so slight, however, that no attempt was made to draw a separate line for each temperature. This concluded the experiment.

There are errors of unknown magnitude in this experimental determination. The reproducibility of these results is believed better than the absolute accuracy, so that the results obtained on these specimens, all tested by the same method, are accurate to about 10 per cent.

A listing of possible sources of error should include the following:

(1) There was appreciable radial heat loss from both specimen and standard.

(2) The system could not be maintained at thermal equilibrium because of fluctuating power supply.

(3) At higher temperatures it has been shown that the thermocouples became loosened because of unequal expansion of

the thermocouple metal and the copper. This caused observed temperatures to be lower than their true values. The seriousness of this error can be appreciated by recalling that a temperature gradient was determined as a small difference of two large numbers. One investigation showed that a one per cent error in the temperature reading caused a 15 per cent error in the temperature gradient.

(4) The type of direct reading potentiometer used could not be read in less than 5°F increments. A potentiometer accurate to 1°F would have been better for the same reason as in paragraph 3.

(5) The porous specimens of 39 and 42 per cent porosities contained cracks and discontinuities which undoubtedly disturbed the heat flow.

To sum up, the precise determination of thermal conductivity is very difficult, first because there is available no perfect thermal insulator to confine the thermal current to the path desired, and second because precise measurements of high temperatures are difficult to obtain.

The best theoretical analysis of the effect of porosity on thermal conductivity is obtained from a comparison with electrical conductivity. The fact that the ratio, for solid metals of thermal conductivity to electrical conductivity is approximately constant at room temperature was first discovered in 1853 by Wiedemann and Franz (Cf. Ref. 3). However, this ratio varies considerably with temperature. Years later, Lorentz (Cf. Ref. 3) showed that by adding a temperature factor to this

ratio, the value should become an universal constant.

The proportionality between thermal conductivity and electrical conductivity established long ago for solid metals appears to hold true for porous metals. Maxwell (Cf. Ref. 4) calculated the electrical conductivity of a structure composed of spheres of one metal dispersed in another and arrived at an equation which may be written

$$K_{Ag} = K_{Cu} \frac{(2K_A + K_{Cu} - P_A(K_A - K_{Cu}))}{(2K_A + K_{Cu} - 2P_A(K_A - K_{Cu}))} \quad \text{where}$$

K_{Ag} is the conductivity of the aggregate, K_{Cu} and K_A are respectively the conductivity of the matrix material and of the dispersed phase, and P_A is the volume fraction of the dispersed phase in the mixture. While this relation is exact only for dispersed particles of spherical shape and for relatively small values of P_A , it gives a reasonable approximation to the experimental results of this thesis.

If we take copper as the matrix and air as the dispersed phase, the electrical conductivity of the aggregate is

$$K_{Ag} = K_{Cu} \frac{(1 - P_A)}{(1 + 2P_A)}$$

where the conductivity of the air is assumed negligible. This agrees generally with the experimental measurements of thermal conductivity, Figure 17. By modifying this equation, an empirical expression which fits the experimental results better can be obtained, as in the equation

$$K_{Ag} = K_{Cu} \frac{(1 - P_A)}{1 + 3.5P_A}$$

These results are graphed in Figure 17.

PART VII
CONCLUSIONS

The experimental study of the thermal conductivity of porous copper has shown that:

1. The thermal conductivity is a decreasing function of porosity, falling off very rapidly for the first few per cent of porosity, and then leveling off.

2. The influence of temperature on both wrought copper and porous copper specimens is identical and almost negligible.

FINAL COMPUTATION

BASIC EQN:

$$K_c \left[\frac{\Delta T}{\Delta l} \right]_c = K_s \left[\frac{\Delta T}{\Delta l} \right]_s$$

WHERE: K_c IS THE UNKNOWN CONDUCTIVITY OF COPPER

K_s IS THE KNOWN CONDUCTIVITY OF IRON

$\left[\frac{\Delta T}{\Delta l} \right]_c, \left[\frac{\Delta T}{\Delta l} \right]_s$ ARE KNOWN TEMP. GRADIENTS

JUNCTION TEMP °F	CONDUCTIVITY OF STAND.	TEMP GRAD. OF STAND.				CONDUCTIVITY OF COPPER	
COPPER NO. 1 - 22% POROUS							
T_j	K_s	$\left[\frac{\Delta T}{\Delta l} \right]_s$	$K_s \left[\frac{\Delta T}{\Delta l} \right]_s$	$\left[\frac{\Delta T}{\Delta l} \right]_c$	K_c		
200	9.00	31.5	288	10.0	28.8	$\times 10^{-4}$	
300	8.56	57.5	492	18.0	27.4		
400	8.12	85.0	690	25.5	27.0		
500	7.67	113.0	866	34.0	25.8		
600	7.24	147.0	1063	41.0	25.8		
700	6.80	178.0	1210	49.0	24.8		
COPPER NO. 2 - 28% POROUS							
T_j	K_s	$\left[\frac{\Delta T}{\Delta l} \right]_s$	$K_s \left[\frac{\Delta T}{\Delta l} \right]_s$	$\left[\frac{\Delta T}{\Delta l} \right]_c$	K_c
