ABSTRACT
Southern Peru represents a subduction transition region from normal subduction in the
southernmost part of Peru to flat slab subduction in central Peru. In order to learn more about the
structure of southern Peru, causes of flat slab subduction, and the nature of the transition from
normal to flat slab subduction, we installed three seismic arrays utilizing a total of about 100
broadband stations. The first installed array samples the normal subduction region, while the
second samples the transition from normal to flat subduction, and the third samples the flat slab
region near where the Nazca Ridge is presently subducting. Data from teleseismic events greater
than 30 degrees distance from Peru was analyzed using the receiver function method that makes
use of P to S converted phases at interfaces such as the Moho to provide information about the
structure directly beneath each station. A strong signal from the Moho was observed for each
array and was found to have a maximum depth of around 75 km beneath the Altiplano. The
average crustal Vp/Vs ratio was also estimated and was found to have an average value of around
1.75 beneath the Altiplano. The shape of the slab was also clarified for the three arrays. The
transition from normal to flat slab subduction appears to be a contortion rather than a break in the
slab. In addition to those signals, a positive impedance midcrustal signal at about 40 km depth
was widely observed for stations on the eastern side of the arrays. The midcrustal signal is
indicative of a velocity increase in the lower crust and is suggested to be an observation of the
underthrusting Brazilian shield which would have implications for the timing of uplift in the
Andes. Finite difference modeling with velocity models that include a midcrustal structure
produces synthetics which are consistent with receiver function observations. Receiver function
results and other related methods provide a simple way of making direct observations of key
structural interfaces and the current state of the subduction system which has relevance in studies
of the tectonic evolution of the region and estimations of causes of flat slab subduction.

NOMENCLATURE

Subduction. Describes the movement of two tectonic plates in which a denser plate is forced beneath the lithosphere of a less dense plate.

Normal subduction. Subduction in which the descending plate subducts at an intermediate angle close to 30 degrees.

Flat slab subduction. Subduction in which the descending plate subducts at a very shallow angle of less than 10 degrees for a portion of the subduction length. For example a plate which initially starts off subducting at a steep angle near the trench but flattens out to subduct almost horizontally beneath the overriding plate for a distance of several hundred kilometers before resuming subduction at a steeper dip angle would be considered flat slab subduction.

Underthrusting. A process during compression in which one rock body is thrust beneath another relatively stable rock structure.

Shield. Typically refers to exposed precambian igneous and metamorphic rocks that form the stable interior of the continent.

Moho. Short for Mohorovičić Discontinuity, the boundary between the crust and mantle marked by a seismic velocity increase.

Tectonic plate/slab. Consists of lithosphere which is able to move on top of the viscous asthenosphere and interacts with other plates in a variety of tectonic settings such as subduction zones, strike slip regions, or divergent settings. A tectonic plate or slab includes continental or oceanic crust as well as mantle lithosphere. When used in the context of receiver functions, “slab” or “slab signal” is sometimes used to reference the subducting oceanic crust which is marked by receiver function pulses. However the subducting plate is understood to include the full lithosphere.
Chapter 1: Introduction and Summary

The following chapters provide details of the methods, analysis, results, and discussion of seismic data collected by arrays of seismic stations installed in southern Peru. Each chapter is structured as a self-contained paper and will have its own set of references at the end. The second chapter is in press with Journal of Geophysical Research-Solid Earth, while the third chapter was recently submitted to Geophysical Journal International.

The subduction style of the Nazca plate beneath South America varies along strike from areas of “normal subduction” where the slab dips at angles around 25°-30°, to areas of flat slab subduction where the Nazca plate subducts at an angle less than 10° beneath South America, as observed from seismicity in the Wadati-Benioff zone. Areas of normal subduction include southern Ecuador (~0°-2° S), southern Peru/northern Chile (~15°-27° S), and southern Chile (~33°-45° S). Areas of flat slab subduction include central and northern Peru (2°-15° S), central Chile (~27°-33° S) and central Ecuador (0°-2° N) (Barazangi and Isacks 1976). Southern Peru represents a transition from normal to flat slab subduction. Three seismic arrays were arranged roughly in the shape of a box to sample the region of normal subduction (perpendicular to the trench), transition from normal to flat slab subduction (parallel to the trench), and region of flat slab subduction (perpendicular to the trench).
Figure 1.1. Topography and bathymetry map of Peru showing slab contours from the Slab 1.0 model. The seismic arrays are shown as red circles. Orange circles denote added stations from the CAUGHT/PULSE experiments. Dormant/active volcanoes are shown as blue/yellow triangles.

The purpose of the project is to clarify the structure beneath the arrays to learn more about the present state of the subduction system, compare the normal and flat slab regions, and study the nature of the transition between the two subduction regimes. Overarching questions which stem from these observables are what are primary causes of flab slab subduction in Peru and what is the tectonic evolution of the area.
The array in the flat slab region is located near where the Nazca Ridge is presently subducting and can be useful in estimating the effect of the ridge on the subduction system. The thickened crust from subducting oceanic ridges, plateaus, and other such impactors has been suggested to be a possible cause or contributor to flat slab subduction by adding to the buoyancy of the subducting plate (Gutscher, Olivet, et al. 1999; Gutscher, Malavielle, et al. 1999, Gutscher et al. 2000; van Hunen et al. 2002a, 2002b, 2004; McGeary et al. 1985, and Rosenbaum and Mo 2011). This notion is supported by observations that many flat slab regions have corresponding buoyant impactors such as the Juan Fernandez ridge in Chile and the Carnegie Ridge in Ecuador. A difference between Peru and other flat slab regions is that the flat slab region in Peru is over 1500 km in length which is about three times the length of many other flat slab regions. The Nazca Ridge has been migrating south through time and is located near the southern end of the flat slab region but is not expected to have enough buoyancy to support the length of the flat slab region or keep the slab from returning to a normal dip angle in its wake.

The array in the normal subduction region intersects the present active volcanic arc which ends at the southern end of the flat segment where there is a volcanic gap. Gaps in volcanism are observable in many flat slab regions because the lack of asthenospheric wedge between the subducting and overlying plates inhibits partial melting (Gutcher, Malavielle, et al. 1999). A look at the migration of the volcanic arc through time provides information about the tectonic evolution of a region. For example when a steeply dipping slab begins to flatten, the arc is seen to advance or migrate inland away from the trench as is observed in Chile (Hascke 2002; Kay and Abbruzi 1996; Kay et al.
As a flat slab begins to steepen again (or “roll back”), the volcanic arc is seen to move toward the trench which is thought to be happening in Mexico (Ferrari et al., 2001). In some areas both processes can be observed as the volcanic arc first migrates away from the trench and later migrates back to the trench as happened in western North America during the Laramide (Saleeby 2003). In Peru the volcanic arc was observed to move eastward before extinguishing (Soler and Bonhomme, 1990) and over time as the slab begins to steepen due to eclogitization and increasing pull from the already subducted material the arc will begin to migrate westward again.

The second chapter in this work presents results from “Line 1” running from Mollendo to Juliaca in the normal slab region where the slab is seen to be dipping at 30 degrees. The receiver function method is used to provide direct information about the structure beneath the stations. Signals are observed from the Moho at the base of the crust and the top of the subducting Nazca plate. One of the key observations is of a strong midcrustal positive impedance signal at 40 km depth beneath the eastern portion of the array where the Moho depth is observed to be around 70-75 km beneath the Altiplano. This is suggested to be a possible observation of the underthrusting of the Brazilian Shield which other authors have suggested underthrusts as far as the Eastern Cordillera (McQuarrie et al., 2005; Gubbels et al. 1993; Lamb and Hoke 1997; Beck and Zandt 2002). We suggest here that it underthrusts farther beneath southern Peru and even underlies a portion of the Altiplano. Such an observation has implications for the timing of uplift in the Altiplano. We suggest that the underthrusting of the Brazilian shield is more consistent with a gradual uplift model over the last 40 Ma rather than rapid uplift over the past 10 Ma caused by lithospheric delamination. Although such delamination and rapid uplift may
have occurred further south in the Andes in the Puna Plateau, we suggest that the dominant mechanisms for uplift in the Altiplano of southern Peru are crustal shortening accompanied by tectonic underthrusting from the Brazilian craton.

The third chapter presents results from “Line 2” and “Line 3” in the transition from normal to flat slab subduction and flat slab regions respectively. Line 2 shows the clearest signal from the midcrustal structure at 40 km depth. The shape of the slab is observed and is suggested to be a contortion rather than a tear in the slab. Results from Line 3 show the slab flattening out almost horizontally beneath the Altiplano at a depth of about 100 km. Results from this array are compared to the results from Line 1 in the normal subduction region.

The fourth chapter presents further details of the methods used including methods which are not presented in the papers. The results from this project are part of the PeruSE (Peru Seismic Experiment) which began with field work and installation of broadband seismic stations in 2008. The details of installation and seismic equipment used are presented. The second array was installed and began collecting data in late 2009 while half of the third array began collecting data in late 2010. The installation of the third array was completed in 2011. After the collection of seismic data, teleseismic events were analyzed with distances greater than 30 degrees and magnitudes greater than 5.8. The receiver function method was used to provide more information about the structure beneath the stations using deconvolution in the frequency domain. Both these results and results using iterative time domain deconvolution are described. Although most receiver function studies focus on P waves which convert to S waves at impedance contrasts, the
great distance of many events from Peru made it useful to be able to include PP and PKP phases. Results are compared using the various P-based phases to show the compatibility of the receiver functions using the different phases. In addition to P, PP, and PKP phases, S wave receiver functions were also attempted which have been used to look for the lithosphere-asthenosphere boundary (LAB). Multiple receiver functions for each station from similar azimuthal directions are stacked to obtain estimates for Moho depth and Vp/Vs from the maximum summation of receiver functions at the time of the converted phase and multiples. Although most of the analysis is done with radial receiver function, transverse receiver functions were also analyzed. The presence of energy on the transverse component can be suggestive of either a dipping interface or anisotropy. The structure beneath the stations, including interfaces such as the Moho and subducting oceanic crust can be clarified by plotting the amplitudes of receiver functions in cross section using methods such as backprojecting rays and CCP (common conversion point stacking). The backprojection method assumes an approximately linear ray path and plots the amplitudes of receiver functions from the direction in which the energy arrived so that each point along the receiver function is at the correct depth and distance from the station. The amplitude at any given point in the image is an average of the amplitudes of receiver functions which pass through that point. The CCP method is similar except it calculates the piercing point of the ray with the expected depth of the Moho. All other rays which pass through this region are stacked and the resulting stacks are plotted. The receiver function methods use an average P wave velocity model. Simple 2D velocity models are tested using finite difference modeling. Two different methods are used to model both teleseismic energy to produce synthetic receiver functions, and to model local
events allowing for the comparison of synthetic seismograms with data. Local events were also analyzed but further analysis of local earthquakes is an area for future study.

In summary, the receiver function results shown in these chapters clarify the structure beneath southern Peru to elucidate the present state of the subduction system. Results are compared for the normal and flat slab regions which has implications for studying the causes of flat slab subduction. The transition from normal to flat slab subduction is also observed.
